FIG. 4.—Case of abdominothoracic penetrating bullet wound. The bullet entered just above the right costal margin close to the xiphisternum, penetrated liver, and lodged behind in the tenth left interspace. Patient had severe pain. Right hemothorax followed, which was aspirated. Patient made an excellent recovery, the bullet being left *in situ*. (Radiograph by Mr. Shenton.)

from the skin or clothing, from the septic entrance or exit wounds, from the septic bullet track, from systemic infection derived from a septic wound elsewhere (pyemic), from open air infection in the case of large shell or shrapnel wounds, or by communication with a hollow tube or viscus in the abdomen. It must also be noted that Sir George Makins, in his *Surgical Experiences in the South African War*, describes many cases of secondary empyema following incision of the chest or aspiration. The writer has certainly seen one case of pyothorax following the removal of a bullet lying immediately under the skin, the incision being merely an extension of the original skin wound. Apart from the evidence afforded by exploratory puncture, the continuance of pyrexia beyond a fortnight—especially if it is of a swinging, hectic character—is very suggestive of pyohemothorax. In two cases under the writer's care, in which exploration was not resorted to until late, severe pain, continuous pleuritic friction, and, in one

of the cases, pleuropericardial friction, were prominent features.

The treatment of a pyohemothorax and the much rarer uncomplicated empyema is identical, viz., early rib resection and evacuation, with free drainage, the prognosis depending, as in the case of empyemata in civil practice, on the nature of the causal organism. Streptococcal cases are the most serious, whereas septic effusions, due to staphylococci or pneumococci, as well as to anaerobic bacilli, generally do well. The writer has a strong belief in the value of vaccine therapy, particularly in streptococcal cases, and in his opinion it is well to begin the treatment soon after operation. Sensitized and autogenous vaccines are specially useful. They should certainly be resorted to if the pyothorax continues to discharge after a month or six weeks.

c. Simple serofibrinous pleurisy. Localized friction is often heard for a few days, but rapidly disappears in the sterile cases. Simple pleurisy with clear serous effusion is very rare after gunshot wounds, though Colonel Hale White has described a case. It is probable, however, that in all cases of hemothorax there is a certain amount of associated pleurisy, the presence of the blood acting as an inflammatory irritant. This inflammatory reaction is probably the cause of the mild pyrexia which characterizes a sterile pneumothorax during the first one or two weeks after its occurrence. The enumeration of the red corpuscles in the fluid, obtained on exploration in hemothorax, has been done with the view of determining the proportion of pleural exudate, but the early clotting of the blood in the pleural sac in cases of hemothorax makes such a method of doubtful value.

Pneumothorax and hemopneumothorax. Delorme states that partial pneumothorax is a frequent concomitant of hemothorax, whereas recent English observers are of opinion that it is a rare condition. Thus, in Colonel Hale White's series of fifty cases pneumothorax was present only twice, and Sir George Makins stated that this complication is exceedingly rare with bullet wounds. In Bradford and Elliott's series of 450 cases of hemothorax, only eight indubitable examples of pronounced pneumothorax, with complete pulmonary collapse, were met, while there were only four cases of complete pneumothorax without blood. These twelve cases were all right sided—possibly because the left sided cases proved fatal from heart injury or heart failure before the patients could be transferred to the base. Rose Bradford recommends aspirating the air-containing space first, and opening the pleura afterward, when the lung has partially expanded. It is probable that small temporary air effusions are comparatively common immediately after a perforating injury of the chest and may often escape observation, for the absorption of the air is an extremely rapid process, and the condition may exist for one or two days only, owing to the rapid sealing up of the lung wound, there being no valvular opening into the lung, as in pulmonary tuberculosis. It has already been pointed out that the Skodaic tympanitic resonance above the area of the effusion often leads to a mistaken diagnosis of pneumothorax from misinterpretation of the characteristic phenomena. An x ray examination is of value in the diagnosis of pneumohemothorax. If air is present in any considerable quantity above the blood, the upper level of the fluid is horizontal when the patient sits up on the x ray couch, and it is stated that wavelike oscillations are visible in the fluid when examined through the fluorescent screen in uncomplicated hemothorax; on the other hand the upper surface of the fluid opacity is irregular and slanting. The writer has no experience of the pneumohemothorax caused by gas forming bacilli.

While dealing with the subject of air effusions, we may mention, *en passant,* the fairly frequent occurrence of subcutaneous emphysema in penetrating wounds of the chest. This condition, however, is of surgical rather than medical interest, except so far as the characteristic auscultatory phenomena may be misleading.

INJURIES OF LUNGS.

Delorme states that the bullet track in the lung is smooth, and not lacerated, and that the walls of the canal adhere, owing to the elasticity of the lung tissue, the canal itself being slightly suffused with blood. According to the velocity of the bullet and the portion of the lung affected, we may have fissures, furrows, cul-de-sac wounds, or total perforations. Owing to the yielding nature of the lung parenchyma, the bullet usually passes right through, and if it has not escaped by an exit wound, is often found in the pleural cavity. The bullet track may have a considerable amount of blood infarction around it, and the writer has seen a postmortem specimen in which the infarction approximated to the dimensions of the middle finger. The aperture of entry may look like a small red spot, about three mm. in diameter, with the aperture of exit somewhat larger. A shrapnel bullet forms a larger track, the aperture of "entry" being more rounded than slitlike, and that of "exit" more extensive and irregular. Laurent states that the sanguineous trail indicating the bullet track is undiscoverable at the end of a week, and it is probable that the elastic character of the lung, which keeps the walls of the track in apposition, rapidly seals up fairly large bloodvessels, and even bronchi which have been torn across by the passage of the missile. Bullets and metallic foreign bodies have a tendency to find their way into the pleural cul-de-sac. Unless the presence of a bullet is giving rise to definite symptoms, it is best to leave it *in situ,* and not to attempt its removal from either the lung or the pleural cavity.

The principal symptom of lung injury is, of course, hemoptysis, though, as already explained, a slight hemoptysis may occur from mere bruising of the lung, without actual penetration. The hemoptysis following perforating wounds of the chest is never severe. Laurent found hemoptysis in seventy-five per cent. of wounds of the lungs. It was present in seventy per cent. of the writer's cases. The hemorrhage varies greatly in amount, from a mere staining to a moderate amount of bright red blood. The staining may occur immediately, or after the lapse of two or three days. It is common for an irritating cough to develop just after the injury, and for the expectoration to become rapidly tinged with blood. After a few days hemoptysis ceases—often almost

suddenly—and, as a rule, it does not recur. The bleeding is rarely profuse enough to give rise to danger, except when a large bloodvessel and bronchus at the root of the lung have been perforated, in which case the hemoptysis is generally rapidly fatal. A late hemoptysis coming on five to ten days after the injury is occasionally met, owing, no doubt, to the occurrence of blood infarction around the wound track.

Pneumonia is, fortunately, an extremely rare complication, and more often occurs on the opposite side. Pulmonary abscess and gangrene are also rare phenomena, for the bullet track in the lung is, as a general rule, sterile, and infected areas within the lung substance are rarely developed, while any contusion or laceration which may have occurred tends to heal readily. When gangrene or abscess does occur, it is usually in connection with shrapnel and shell wounds.

INJURIES OF THE HEART AND GREAT BLOODVESSELS.

Perforating wounds in the highly dangerous central zone of the thorax are, as a rule, rapidly fatal. Wounds about the clavicle are extremely dangerous, owing to the proximity of the large vessels and nerves at the root of the neck, and if these are wounded, the patient nearly always dies on the battlefield. It is quite extraordinary, however, how often these important structures in the chest are evaded, when, judging by the line of the bullet as indicated by the position of the entrance and exit wounds, it would seem almost impossible for one or more of them to have escaped. This is particularly noticeable in the case of the large bloodvessels.

CASE III. A New Zealander was admitted under the writer's care at Hampstead Military Hospital, who had been wounded in Gallipoli, by a bullet which entered below the right clavicle; passed right through the chest, perforating the blade of the scapula, and now lay under the skin below the spine of the right scapula, where it could be readily felt. He spat blood for ten days after being wounded. He made an excellent recovery with no untoward symptoms, thus indicating the absence of serious injury to any of the numerous important vascular and nervous structures.

CASE IV. A case was recently admitted to the Royal Chest Hospital, in which a bullet traversed the upper part of the chest, producing a small, traumatic, pulsatile aneurysm above the sternal end of the left clavicle and also an injury of the left phrenic nerve, indicated by paralysis of the left half of the diaphragm, which, as shown by the fluorescent x ray screen, ascended when the opposite side descended with inspiration; no other symptoms developed, and the patient made an excellent recovery.

Colonel Hale White recently recorded an injury to the left recurrent laryngeal nerve, without involvement of the aorta or other adjacent important vascular or nervous structures.

Mr. Keogh Murphy[1] describes a case of severance of the subclavian artery, the proximal end of the divided artery having become sealed by organized blood clot and the pressure of the surrounding tissues. He has seen four cases in which, from the line taken by the bullet, it would appear that the heart must have been perforated in several places, and yet, apart from slowness of the pulse, there was no disturbance of the heart action, and in only one of these was there pericardial friction. Mr. Murphy, while operating in a case of pyothorax, observed a bullet track ascending along the right ventricle, on to the right auricle, without producing actual perforation. Grazing wounds of the heart are probably the cause of the pericardial friction, which is often heard when the bullet has gone near the heart.

At a recent meeting of the West London Medical Society, Major McAdam Eccles showed a patient alive and well, who was admitted to St. Bartholomew's Hospital with left hemothorax and hemopericardium, and in whom the x rays showed a bullet situated in the muscular tissue of the septum of the heart, the bullet having entered the thorax a little below and internal to the coracoid process of the left scapula, traversed the left lung, fracturing the posterior part of the left fourth rib, and was then deflected forward into the heart. With the x ray fluorescent screen the bullet could be seen moving synchronously with the contractions of the heart. The extraordinary clinical fact in the history of this case was, that immediately after being struck, the man was able to walk to the Ypres hospital, a mile and a half away.

In the *Journal of the Royal Army Medical Corps* for October, 1915, a case is recorded by Lieutenant Birkbeck and Lieutenant Lorimer, in which a bullet was removed by Colonel H. M. W. Gray from the cavity of the right ventricle, under a local anesthetic. The patient was admitted to hospital eight days after being wounded by a bullet, which, after killing the man just in front of him, entered his chest just below and to the right of the xiphisternal junction. The patient was kept at rest, and for some days no symptoms manifested themselves, the pulse averaging 80 to 90, and the evening temperature varying from 100° to 101° F. An x ray examination revealed the bullet shadow moving synchronously with the heart. A week after admission there was some cardiac irregularity, with occasional dropped beats, and it was decided to operate and remove the bullet. The patient lived for four and a half days after the operation, and the post mortem examination showed that the cause of death was multiple pulmonary embolisms, the clots being derived from the right ventricle. Colonel Gray, in commenting on the case, mentions that a French surgeon had recently removed, with permanent success, a rifle bullet which had lain in the left ventricle for five months.

In nonfatal grazing wounds and other injuries of the heart, there are often no symptoms other than occasional slowness or irregularity of the pulse, though pericardial friction may sometimes be heard. In all injuries involving the heart and great vessels, expectant treatment is naturally the only course to adopt, with absolute rest, absence of all excitement, and the use of effective doses of morphine.

It has already been mentioned that pleuropericardial friction is not unfrequently present in left pyohemothorax. Suppurative pericarditis has been described, and has been successfully treated by drainage of the pericardium. Hemopericardium is rarely consistent with life, though it was present and apparently caused no embarrassment of the heart in Major Eccles's case just referred to.

3. *Complicated injuries.* In thoracicoabdominal wounds, the abdominal lesion may be the dominating factor in the situation, and rest, with judicious non-

[1] Keogh Murphy, *Wounds in the Thorax in War*, 1915.

interference, is the policy to be adopted. In many cases, however, the fact of the bullet penetrating the diaphragm and emerging in the abdominal wall seems to make very little material difference if the hollow viscera are not injured. It is important to remember the great elevation of the dome of the diaphragm. The vault of the diaphragm reaches to the level of the fifth, it may be of the fourth rib on the left side. Accordingly, when an anteroposterior traverse penetrating wound occurs below the level of the fifth rib, the wound becomes thoracicoabdominal. Abdominal complications are, however, commoner in longitudinal wounds of the chest. Vomiting and hiccough in gunshot injuries of the chest should make one strongly suspect a perforating injury of the diaphragm. The organs most likely to be injured in thoracicoabdominal wounds are the stomach, liver, spleen, and kidney. On the right side the liver is frequently injured, but grave symptoms rarely follow, and jaundice does not occur. The writer had recently under his care a soldier wounded in Gallipoli, in whom the bullet had entered just above the right costal margin, and, after piercing the liver, ultimately lodged behind it in the pleural cavity below the tenth rib. The patient acquired hemothorax (sterile), but made an uninterrupted recovery. (Fig. 4.)

Captain T. R. Elliott and Captain Henry have described a case of cholohemothorax. The bullet, after drilling a hole through the left arm above the elbow, entered the chest behind the sternum close to the base of the heart, and passed out through the right side, injuring both liver and lung. A large right hemothorax developed, and was aspirated. Dry pericarditis then ensued. The fluid in the chest reaccumulated, and this time the aspirated fluid contained bile. Recurrent aspirations had to be performed on five occasions, and altogether fifteen pints of bile were withdrawn. There was no jaundice. Recovery took place at the end of the fourth month.

Wounds involving the thorax and upper abdomen may occasionally be followed by a subphrenic abscess—an extremely serious complication. Perforation of the diaphragm on the left side has been known to result in diaphragmatic hernia, the diagnosis of which is one of extreme difficulty, and has been made with accuracy in only seven out of 300 cases recorded in medical literature. In lateral transverse perforating wounds of the thorax, it is common for the bullet to cause a perforating wound of one or other segment of the upper extremities, while in the longitudinal wounds of the cervicothoracic cases there may be serious cervical as well as thoracic injuries. Injuries of the trachea, large bronchi, and esophagus may occur in perforating wounds, involving the central zone or mediastinum, and are generally rapidly fatal.

PROGNOSIS IN CHEST INJURIES.

The main facts in regard to prognosis have already been referred to. As regards the mortality from perforating injuries of the chest, it is extremely interesting to note the different effects at different periods. In the American Civil War, the average mortality for the large bore bullets was as high as 32.5 per cent. In the Crimean war, the mortality of penetrating wounds of the chest in the British army was over seventy per cent., while in the Boer war it was only 13.4 to 18.4 per cent. (Makins.) At the battle of Mukden, the mortality in the Japanese army was said to be actually under four per cent. This remarkable reduction in mortality is due to the introduction of the modern, small, high velocity bullets. In reference to the present European war, no comprehensive statistics are yet available. It has already been mentioned that in Bradford and Elliott's series of 450 cases of perforating wounds with hemothorax, the total mortality was only ten per cent., and this notwithstanding the frequent occurrence of sepsis, so characteristic of wounds received in the trenches of France and Flanders, it must, however, be remembered that this series of cases did not include the chest wounds that proved fatal on the field of battle.

In contrasting the experience in the present war with that in the Boer war, it may be stated that the high velocity bullets at short range, and the fragments of high explosive shells cause greater laceration than was the case in South Africa, with proportionately greater hemorrhage, while the skin and clothing of the soldiers are so saturated with fecal organisms in the trenches, derived from the manured soil of the agricultural country of Flanders, that sepsis is a much more serious matter than it was in the Boer war.

Many cases must have been saved by the modern excellent motor ambulance arrangements, enabling stretcher cases to be conveyed to the field and base hospitals in comparative comfort, while in the ambulance trains there is every facility for emergency measures, including not only the dressing of the external wounds and injections of morphine, pituitrin, or adrenaline for the relief of pain, dyspnea, or shock, but also saline injections when these are indicated, as in profound collapse.

Appropriate breathing exercises, such as those advocated by Mr. Cortlandt MacMahon (*Lancet*, Oct. 2, 1915) are most valuable for expanding the lungs. Inspiratory exercises with Woolfe's bottles may be used with advantage after hemothorax for increasing the respiratory capacity and promoting expansion, just as in cases of pleurisy with effusion occurring in civil practice. An excellent example of the value of breathing exercises is afforded by the young officer already alluded to who had a left hemothorax, which was not aspirated. The patient, an amateur singer, had prior to the war received breathing lessons for the diaphragm, and began breathing exercises a fortnight after his admission to the hospital for wounded officers. The fluid was quickly absorbed, and, after leaving hospital, the patient took walking and swimming exercise. In six weeks the movement of the left diaphragm was so perfect that, apart from the fractured ribs, it was difficult to tell with the fluorescent screen which was the affected lung, both sides moving equally well. (Fig. 2.) After a few months' convalescence he was able to return to the fighting line.

In addition to breathing exercises, hill climbing is excellent for expanding the lungs, the patient gradually increasing the distance and attempting steeper ascents as his progress continues.

EXTENSIVE SUBDURAL HEMORRHAGE AFTER TRAUMA.

With Mental Disturbances Due to Involvement of the Right Frontal Lobe; Operation; Cure.

By B. Sachs, M. D.,
New York;
And Charles A. Elsberg, M. D.,
New York.
(From the Neurological and Surgical Services of Mount Sinai Hospital.)

During the past year we have observed the following case, which is of interest both because of the extent of the lesion and of the prompt and complete recovery after the second operation. The mental symptoms increased the difficulties of diagnosis and are especially worthy of note.

Case. Early in August, 1915, H. S., thirty-eight years of age, a man of unusually strong physique, was thrown out of an open automobile, landing on a country road on the

Fig. 1.—Osteoplastic flap turned down and dural flap reflected. Exposed brain covered by layer of organized blood clot.

right shoulder. He was picked up in an unconscious state and was taken care of for a time at a farm house. He regained consciousness after a few hours and seemed to have suffered so little from the accident that he was able to travel on for some distance and was under the charge of an osteopath until the early part of October. The skull was x rayed at an Albany hospital, and, so far as we know, the findings were negative.

The only change observed by those around him was that his mental condition seemed to have been altered; that he was more talkative than he had previously been and at times laughed immoderately without cause. He was otherwise well and able to attend to business until October 15, 1915. On that day he consulted his family physician, Dr. Albert Kohn, who at once referred him to Doctor Sachs. To both physicians he stated that three days previously, while at a hotel in Cleveland, he slipped in trying to get out of the bath tub and gave his head a hard knock. He became unconscious; forty-five minutes later he heard a bellboy knock at the door. He called to have the boy come in and then realized that he had given his head a severe blow. He was helped out of the bath tub and was able to walk, but realized that his left hand was weak and that he had some difficulty in using his left leg. He was well enough to travel from Cleveland to Detroit, dragging his leg, and annoyed only by the fact that he was dropping his grip. As he expressed it, he was able to walk, but stepped into things. He would knock against everything and everyone.

When questioned further about his general condition, he confessed that ever since the first accident he became easily drowsy, but not to such an extent as to be prevented from attending to his ordinary business affairs. On the evening of October 14th, he took his ticket to Detroit and slept well during the night, but found that he could not undress himself. In fact, for a few days, he had to have help in dressing and undressing. He also confessed that he had been suffering from headaches for some time before the bathtub accident.

On examination, it was found that the left arm was limp and that the lower two thirds of the left arm and hand showed slight disturbances of all forms of sensation. The muscle sense was entirely normal. The reflexes were not increased either in the left upper or left lower extremity. The motion of the right upper extremity was limited, but this was evidently the result of the original auto injury, when he struck his right shoulder.

At this examination both legs were weak, the patient asserting that the left leg did not "feel heavy" before the second accident. Both feet stubbed the ground easily. He was positive that the right hand did not grow worse after the second accident. He also noted that there was a very slight left facial paresis.

As a result of this first examination the diagnosis of extensive hemorrhage or abscess was considered probable and the patient was advised to go to Mt. Sinai Hospital. The question of operation was at once considered with Doctor Elsberg, and from this time on the patient remained under the care of Doctor Kohn and of the authors of this paper.

In addition to the hemiplegia, the mental condition of the patient attracted our full attention and was for a time somewhat puzzling. At the hospital the patient was extremely noisy; would answer some questions correctly, more often incorrectly. He became extremely vulgar in his speech and was given to inordinate jesting and punning, exhibiting the usual *Witzelsucht* (effort to be funny). After a few days the patient became more drowsy. The left upper extremity became completely paralyzed, not spastic; the left half of the face was involved, and the left lower extremity was more paretic. Although he was well able to stand, he walked with great difficulty. The left upper extremity and the left half of the face were distinctly anesthetic. The sensory disturbances were much less marked in the lower extremity. There was no apraxia or astereognosis so far as these could be satisfactorily determined.

As for other symptoms, he complained of severe frontal headaches; the pupils reacted sluggishly to light and accommodation, the right being larger than the left, and there was a papilledema of more than three diopters in each eye. The abdominal reflexes were present on the right side, but could not be elicited on the left.

While in the hospital the patient was seen by Dr. I. Strauss, who did the lumbar puncture, withdrawing about ten c. c. of clear fluid under increased pressure (230 mm.). The Wassermann was negative and there was no increase of cells or globulin.

On October 26th, the symptoms had increased to such an alarming extent that we decided to do an exploratory operation, particularly as the right optic nerve showed numerous small hemorrhages.

A button of bone was removed in front of the middle of the right motor area and the dura was incised. A large quantity of dark colored fluid escaped. In the depths of the opening the brain could be indistinctly seen. After the fluid had been removed by gauze sponges and more bone had been rongeured away in the subtemporal region for decompressive purposes, the wound was closed without drainage.

It is a fair question whether it would not have been wiser at this time to make a larger incision and expose the greater part of the area involved in the lesion. The patient recovered from this operation,

but his condition was not improved. Hemiplegia was complete, and, although the patient was less drowsy, he did not recognize those about him. He was still noisy and could not be quieted with large doses of hyoscine and morphine. Urination and

FIG. 2.—The organized clot has been partly peeled off, exposing the brain underneath.

defecation remained involuntary. The eye grounds failed to show improvement. Although there seemed to be some slight improvement in the movement of the left upper extremity, we concluded after further consultation that a second and larger operation was our only hope of rescuing the patient. The continuance of the mental symptoms impressed us with the probability of an involvement of the frontal lobe, and it was evident that the lesion was a very extensive one. We were still somewhat in doubt whether we should find a large hemorrhage or an abscess. At no time during his illness did the patient exhibit any considerable rise of temperature and all the symptoms could have been explained as the result of either hemorrhage or an old chronic abscess.

On November 15th, Doctor Elsberg turned down a large osteoplastic flap in the right frontoparietal region. When the dura was incised, much dark fluid blood escaped and the brain was found to be about two inches from the bone and without pulsation (Fig. 1). The cortex was covered by an organized layer of blood clot 0.5 cm. in thickness, which had evidently compressed the parietal and frontal lobes. So great was the compression that the examining finger could palpate the bony roof of the orbit and the greater part of the floor of the anterior fossa on the right side. The layer of tissue which held down the brain was incised and the operator found that he could peel it off in strips, exposing the normal looking cortex underneath. When the greater part of the layer of organized tissue had been removed in this manner (Fig. 2), the brain began to expand and to pulsate normally. Over the outer aspect of the frontal lobe the brain tissue was somewhat soft over a small area which was covered by newly formed bloodvessels (Fig. 3). The dural incision was then closed by interrupted sutures, the bone flap returned into place, and the scalp wound sutured.

The wound healed by primary union. The morning after the operation, the patient was able to move the left arm and leg and the left facial paralysis was less marked. He was restless and his mental condition was not different from what it had been for weeks before the operation. For a few days he was noisy, but then the mental condition gradually changed so that he became more quiet. He began to jest with his nurses and seemed for a time to take special delight in calling the nurses by silly names. He had various delusions. Among other things, he constantly accused his physicians of owing him money, and one day he grew excited because he believed that his ten year old son had been married to his cook. He was especially prone to joke about sexual matters and seemed to derive much amusement from the fact that he voided his bladder into the bed. When asked whether he knew what he was doing he would respond that he did and that he did not care. At various times, he pulled the dressings from his head and always denied that he had done so.

After the fourth or fifth day, distinct lucid intervals occurred, and ten days after the operation he had regained complete control over his mental faculties, and also was able to move the left arm and leg freely, while the left facial paralysis had completely disappeared. The swelling of the discs by this time had also been considerably diminished. He was discharged from the hospital on December 9th, twenty-four days after the second operation. His mental and physical condition was normal in all respects. The fundi were normal and his left arm and left leg

FIG. 3.—All of the clot has been removed, showing an area of brain covered by newly formed bloodvessels.

were as strong as those of the right side. The abdominal reflexes and the extremity reflexes were equal on both sides.

On December 18, 1915, he insisted that he be allowed to take a business trip to Europe. In spite of

the advice of all physicians, he left for Europe, attended to all his business affairs, and presented himself on his return, three months later, when it was found that he had been well during the period, and reexamination showed that he had recovered in every particular.

COMMENT.

Aside from the unusually satisfactory operative results, it is well to record a case in which the mental symptoms were evidently the result of involvement of the frontal lobe, and it is also worth pointing out that the almost maniacal restlessness of the patient and the talkativeness were much more startling than the somnolence which was observed during the earlier weeks after the original accident.

After all, the compression by a blood clot, be it never so large, is less serious than the invasion of brain tissue by malignant growth, and it is conceivable that, for this reason, mental symptoms associated with tumor of the frontal lobe would be more serious than those observed in this case. Moreover, it is probable that there was frequent, if not continuous oozing, finally leading to the formation of this large subdural clot, and that therefore the brain was compressed and not destroyed by a hemorrhage. Any initial hemorrhage of the size indicated by this clot would, in all probability, have proved instantly fatal.

While the patient was favored in many respects by a fortunate combination of circumstances, it is certain that he owes his life and his complete recovery to the success of the operation. None of us had ever seen so large and extensive a clot removed from the brain of a living subject.

INFANTILE PARALYSIS.

With Especial Reference to Its Treatment by Electricity,

By Herman C. Frauenthal, E. E., M. D.,
New York,
Director of Electrical Department, Visiting Orthopedic Surgeon, and Chief of Clinic, Hospital for Deformities and Joint Diseases.

The treatment of this paralytic affection is of such importance that reiteration should act as a stimulus to practitioners and specialists alike; the former to be on the alert to detect the first manifestation of this fearful affliction; the latter to institute proper measures for the treatment. This disease, for convenience, may be divided into four stages, as follows:

a. Acute or febrile stage.
b. Semiacute or stage of hyperesthesia.
c. Period of convalescence.
d. The chronic stage or period of surgery.

THE ACUTE STAGE.

The pathologist tells us that infantile paralysis is a general infection involving principally the cerebrospinal axis. There is a hemorrhagic myelitis, perhaps a mild meningitis, punctate hemorrhages in the cord, most marked in the anterior gray matter, with perivascular infiltration which causes narrowing of the terminal arteries supplying the motor cells, and producing anemia even to the point of necrosis in many of them. The posterior root ganglia may also be involved. If absorption of the infiltration occurs quickly, the anemic cells resume their normal function. During this stage, spinal puncture verifies our diagnosis and blood serum, if used, should be given as early as possible in doses of from six to twelve c. c., repeated the following day. The Hospital for Deformities and Joint Diseases has furnished Dr. George Draper, of the Rockefeller Institute and the State Board of Health, blood serum from many donors. Excellent results are reported when this serum is used sufficiently early. Hexamethylenamine is also recommended, as is adrenaline when the diagnosis is made too late for the administration of serum. The serum obtained from the spinal canal of the patient has been injected into the thigh muscles, in some cases, and, it is stated, with beneficial results. Massive doses of quinine have been given by some practitioners internally, as has echinacea, with alleged benefit. Rest, with quiet surroundings is advised, and symptomatic treatment should be given.

THE SEMIACUTE STAGE.

This stage which begins with the cessation of fever lasts until the disappearance of hyperesthesia. This period varies from a few days, in mild cases, to many weeks, during which time the child should be kept prone, and the muscles paralyzed should be supported by a suitable aluminum, celluloid, or open plaster of Paris splint, or a brace to prevent deformities such as foot drop, flexed knee, flexed thigh, lateral curvature, etc. Little other treatment is necessary during this stage, except that the child should be kept comfortable by warm tub baths, during which the extremities should be gently moved and the child encouraged to make an effort to move them. The brace, of course, is to be removed during the bath.

THE PERIOD OF CONVALESCENCE.

This is the time for active treatment. With the disappearance of hyperesthesia, the process in the cord may be assumed to have reached a stage where therapeutic measures may be begun. This may occur immediately after the febrile stage or may begin many weeks later. We are now ready to take up the active treatment. At this period, the diagnosis of anterior poliomyelitis presents little or no difficulty. The history is one of previous well being with the sudden onset of acute illness, followed by a flaccid paralysis which may affect any or most of the muscles of the body. Atrophy is an early condition in the muscles affected. There is also vasomotor paresis, giving the limb the characteristic blue cold appearance. Reflexes are lost early and the reaction of degeneration in the affected muscles completes the picture.

While considering the advisability of a brace, bear in mind the fact that the ignorant mother whose child wears a brace, often fails to return for treatment, believing that the brace is curative, while its only use is to prevent deformity and to allow ambulatory movements.

Should a brace be deemed necessary, it should be removed daily for the normal use of the limb, and must be discarded when it has served its purpose.

Before applying the brace, it may be necessary to do some tenotomies to place the parts in a functioning position. If the range of motion is limited, perhaps a tenotomy is indicated, a stretching of the shortened muscle, or reefing the lengthened tendon. The limb should be held in an overcorrected position to stretch the opposing muscles. At times, silk tendons are used to steady the joint; then again, the muscle or tendon is transplanted or the joint may be ankylosed or resected.

If a brace is used to prevent or correct a deformity, it should be taken off every day for a few hours, and the child encouraged to make an effort to use the part involved, even if there is no response to the effort. During convalescence, where the arm is involved, the good arm should be placed within the clothes. In all methods of treatment, the mental efforts, without a doubt, play the most important part toward affecting a cure.

Fig.—Children in the convalescent stage after an attack of anterior poliomyelitis.

Continuous attention, not alone by the mother and the physician, but by the patient himself, must be urged, so that the child tries *mentally* to improve the nerve force of the part involved. As a thought conveyed to the brain may induce blushing, laughter, fear, increased appetite, etc., so can a thought improve the circulation of any part of the body and be taught to a child by mental effort. By wearing a brace continuously, the patient loses the value of the mental effort and the physical action and this tends to increase muscular atrophy. Bear in mind that atrophy is synonymous with disuse; use and metabolism go together.

These patients tend to show an improvement for a given time, but sooner or later improvement comes to a standstill; some muscle or muscles seem to have lagged. This is the time for renewed effort or surgical intervention.

The office treatment consists in the application of some form of energy. As we all know, each of the different forms of energy such as heat, light, electricity, vibration, magnetism, sound, nerve force, are converted under certain conditions into one another: nerve force into light as in the firefly, and nerve force into electricity as in the electrical eel.

Any method of treatment that will improve the general health, such as medication, hygiene, fresh air, etc., or that will improve the metabolism of the part involved, is good treatment. This includes massage, vibration, mechanical devices, heat, white light, electricity, and last though not least, psychotherapeutical exercises, or muscle education, with reflecting mirrors so placed that the patient can easily see the part involved. The limb treated must be slightly flexed, when the flexor muscles are involved, so as not to have the muscles strain under treatment by any of the modalities.

In contrast to the belief expressed in the writings of many physicians on the treatment of infantile paralysis by electricity, I know that this has more value than all other methods combined, if used in the proper manner by one who understands which electric modality to use and the method of its application. I feel from my experience at the Hospital for Deformities and Joint Diseases, where I have treated thousands of cases in the past ten years by electricity, and the fact that I am a graduate in the subject of Lehigh University, that I am as competent as, if not more competent, to judge of its efficiency than any other member of the medical profession who has written on the subject.

Dr. Henry W. Frauenthal, in his writings on the comparative value of methods of treatment in infantile paralysis, allows:

Fifty-five per cent. to electricity;
Ten per cent. to massage;
Thirty-five per cent. to physical culture.

In this I heartily agree, and I regret that in my visits to the offices of some eminent orthopedic surgeons, no electric wall plate was seen.

I shall not describe the different forms of electrical currents or their uses, as galvanic, faradic, mixed, d'Arsonval, sinusoidal, high frequency, high tension of Oudin, Tesla, and O'Farrel, for a thorough knowledge of the galvanic is primarily essential to understand the actions of the others; hence, I shall speak only of galvanic electricity which can be very easily obtained from the New York street current. The terms used in galvanic electricity are:

E—voltage—difference of potential or level.
O—ohms—resistance of circuit.
C—ampères—milliampères—the quantity of current used.
Watts—product of E by C.

C—equals $\frac{E}{R}$

Other terms used are multiple, direct, alternating, closing, opening, rheostat, volt meter, milliampère meter, switches, sponges or applicators, etc., which words define themselves. I merely wish to mention here that although I write most on the galvanic current, the other currents are used sometimes to better advantage when they are indicated. I have found of great value the d'Arsonval when used with a series spark gap in producing contraction where none of the other modalities would act.

METHODS OF REGULATING A WALL PLATE.

We have all switches turned off before putting on the main switch which turns on the current from the city main; we select the galvanic current and regulate it with the volt meter. This also regulates the primary faradic current when that current is being used. If we select the combined currents, the amount of current is regulated by the volt meter and the switch in the magnetic coil. If we would use the secondary faradic current alone the amount is regulated on the magnetic coil only. The milliampère meter should be used only in a galvanic current. The sinusoidal is used simply by throwing on the switch and regulating the current with the rheostat of the meter. The galvanic current was originally obtained by placing metals of different electrical potential in a conducting fluid. Zinc is most commonly used as the positive element or negative pole; any other metal may act as a positive pole. Thus our primary battery is made. The method of detecting the pole is to place tips at the end of the electric cord in salt solution. The negative pole gives off the most gas. The positive pole is called the anode, the negative pole is called the cathode. Oxygen, the acids are attracted to the positive pole, and halogens, such as chlorine, bromine, iodine, sulphur. The negative pole attracts the alkalies, hydrogen, and the metals; these travel with the current. If we remember the foregoing, the secret of the chemical physiological action is ours. The positive pole relieves pain, stops hemorrhages, contracts tissues, is astringent, and deposits *metals* in the tissues. The negative is more painful and is used to dissolve tissues, remove hair, increase exudation and for depositing acid in the tissues, etc. Thus, its action is opposite to that of the positive pole.

The positive pole, as we shall see, should be used on paralyzed muscles; the negative pole, which should be larger, is placed centrally in order to regenerate, if possible, the nerve conductivity. The galvanic current acts only on closing or opening the circuit; not at other times; also in increasing and decreasing the current. Contractions are proportionate to the strength and direction of the current. Weak current may give no contraction. If upon a normal nerve or muscle a descending current is used to the limit of exhausting the nerve, and no muscular contraction is then found with the cathode on the muscle, a contraction may be produced by placing the anode on the muscle, thus causing an ascending current. This latter is the current used by preference, with proper interruptions, in the treatment of infantile paralysis.

It is well at this point briefly to review the phenomena of electrical reactions in general to a galvanic current. In a healthy muscle, electrical stimulation from a faradic coil or galvanic current interrupted, produces a sharp response. A paretic muscle gradually loses irritability to response, so that very strong currents are necessary to produce contraction. A good diagnostic point is the feebleness of response and the wormlike character of contraction. In complete reaction of degeneration, the muscles will not react to the strongest faradic or galvanic current. This is only presumptive evidence of degeneration, etc.

The normal reactions are K C C followed by: A C C; A O C; K O C. This reaction is different in degenerate muscles. A O C produces the greatest contraction, so that in the use of the galvanic current it is advisable, for many reasons, to place the anode on the paralyzed muscles. We must not imagine we are going to strengthen a muscle or a nerve by pouring electricity into it. Stress animates; strain destroys tissue.

The time spent in the application of an interrupted galvanic electric current (interrupted eighteen to seventy-two times a minute, synchronous with the pulse) should not exceed five minutes daily, using not over ten milliampères of current, or the least amount that will produce a reaction; it is advisable to use the anode on the paralyzed muscle early, while the cathode, which should be of a very large size, is placed centrally. If the cathode is used upon a paralyzed muscle it must be moved continuously in order to prevent an excoriation. Before the current is used upon the patient, try the current interrupted on yourself, taking the positive pole in one hand and applying the current with the other hand to the patient treated; the negative pole on the patient's spine or sternum. When the muscles contract, wait and repeat, suggesting to the child, at the same time, to contract the muscle. Before electricity is given, the limb should be thoroughly heated and massaged and after being treated the patient goes through a course of voluntary therapeutic exercises, mention of which has been made previously. This educational exercise, undoubtedly, has more therapeutical value than other methods of treatment, with the exception of electricity. It is also used in all forms of paralysis with much benefit, and as before mentioned, the mental effort of the patients should be urged at home, morning, noon, and night.

CHRONIC STAGE.

The best illustration of the treatment in the chronic stage is to describe the management of a case of chronic infantile paralysis.

Case. Sara P., a child from South America, appeared at my office with a history of having had infantile paralysis five years before, her present condition being foot drop, limitation of motion with flexion at the knee owing to the shortened ham strings, lateral curvature. A tenotomy of the tendo Achillis was done and a plaster cast applied to the upper part of the thigh, the foot being placed in an overcorrected position; knee joint still flexed in plaster cast; flexion of knee joint corrected by wedges placed in a slot made transversely in the plaster in back of the knee. In three weeks, after the plaster cast was removed and the reaction of degeneration taken, we found that the opening of the current of certain muscles gave a greater contraction than the closing; especially was this true with the anode on the muscle. If normal, these muscles would act best on a closing current especially with the cathode on the muscle. These reactions were taken on the anterior tibial group. We found that there was no reaction in the anterior tibial muscles themselves, and no reaction in the quadriceps group. The child had now been treated for a year, and wore a splint part of the day, which was removed for mental effort, massage, and electricity. The anode was placed on the degenerated muscles, and the cathode placed centrally on the spine or upon the origin on the muscle treated. Before the electricity was given, the leg was thoroughly warmed by a white light baker and massage. After the electricity was given, the child received instruction in mental movements of the foot. At the end of one year, great improvement was found in the anterior tibial group, but none in the quadriceps or anterior tibial muscle. The child now being over ten years of age and having been paralyzed for seven years, was ready for surgical procedure. We transplanted the biceps and semitendinosus into the tendon of the quadriceps anteriorly; this procedure allowed the child, after a few months, to extend the knee; the foot still being in pronation as a result of the paralysis of the tibialis anticus, we transplanted the extensor longus hallucis to take the place of the paralyzed muscle. This tendon was passed through a hole bored transversely through the first metatarsal bone and looped back upon itself; the approximate portion of the tendon was attached or sewed to the tendon of the extensor longus digitorum. The foot was then put in plaster cast in an overcorrected position, and after three months, treatment was resumed.

The child was discharged later and walks well without a brace. A plaster corset is still used to sustain a paralyzed back. This child did not receive galvanic electricity alone; at times, galvanic and faradic were combined, sometimes faradic was given alone, frequently high frequency currents on the back, and occasionally the disruptive d'Arsonval current.

AFTERTHOUGHTS OF THE EPIDEMIC OF INFANTILE PARALYSIS.

By Beverley Robinson, M. D.,
New York.

Despite the fact that there was much search after the specific cause of the late terrible outbreak, nothing convincing was found. We are still obliged to confess our ignorance and to recur to the time honored statement that an epidemic influence has prevailed. The proof is, as we well know, that cases appear suddenly in widely separated tracts of country; that in some cases children, young men and women and occasionally adults of a certain age have been attacked; that not infrequently, there is no evidence that a possible human carrier of the disease can account for it; that healthy children who are most carefully looked after in every rational way take the disease, and not merely neglected children or those of poor parents.

No system of quarantine, even the most rigid, has prevented the disease from attacking persons at a given time. In all these particulars and others, it is closely allied in my judgment, with the grippe. Again, so far as many symptoms are concerned, it more closely resembles the grippe than any other known affection. True it is that the site of the disease after a few days, is especially the spinal cord and causes the paralytic symptoms, which are lasting and disabling, or indeed, rapidly fatal. Even this may merely be a seat of a poison like that of grippe.

So far as precautionary measures exist, I see no reason to change what is rational in the case of both diseases. Manifestly, when the symptoms of disease are present, it is wisdom to prevent bodily contact with those who are well, and when an epidemic prevails in a known locality, it is sensible, sometimes and when conditions permit, to leave such a place for a time. But this does not mean that there should be an unreasonable stampede and that everyone who can afford it, should seek safety in flight. In the first place, there is no assured safety by so doing, simply because the disease seeks susceptible people and for some unknown reason, may attack them soon in the very place they have gone to for safety. Not a few facts prove this. I have not now in mind instances where the disease developed in a patient who brought it from the infected region whence he came. I mean instances where, after several weeks' absence from an affected place, the child was stricken with spinal paralysis.

I am still of the opinion that by intelligent treatment at the beginning of the disease, its worst effects may be warded off, or appear in only a relatively small proportion of cases.

To me, the simplest and probably the most effective treatment in the beginning of the disease, or as a preventive, is the internal use of ammonium salicylate. This remedy may be supplemented by the local use of carbolated petrolatum introduced into the nares, night and morning. The employment of immunized blood serum injected into the spinal canal has evidently been of great service. But the supply is necessarily limited and it should be only given by an expert and after a very careful examination of the blood donor by a physician of wide experience; otherwise, much harm may result. Obviously, this treatment could not now be given properly, or at all, in many country villages, or isolated regions. The treatment I have recommended may be used by any physician when first called to the case, would do no harm in any event, and might help save many lives, or at least might prevent the worst afterfeatures of the case. Even if it is not so curative as blood serum, it would supplement the latter, and whenever this could not be obtained, would be a saving help in time of greatest need.

The ammonium salicylate has been more valuable to me in the treatment of grippe than any other remedy that I have tried—and I still hope every-

thing from its wider use if another epidemic of infantile paralysis occurs. I plead for it very earnestly, as both preventive and curative. To me, the daily reports from the hospitals of what the physicians are doing is very unfortunate, as they tend to keep alive a condition of great mental anxiety and dread which is not wholly justified by the facts.

Much of the treatment which has been employed in hospitals is experimental and how much of it will remain an acquisition of value is not yet known. Meanwhile, we should be loath to abandon a treatment which has proved itself so valuable, innocent, and simple in a similar disease.

PELVIC MASSAGE.

An Unappreciated Prerequisite of Success in Diseases of Women,

By Ferdinand Herb, M. D.,
Chicago.

During the winter of 1886-1887 a new and epoch making method of treating gynecological afflictions by means of massage was successfully demonstrated to the medical profession by Thure Brandt, of Sweden, who had devoted a lifetime of observation and study to the subject. The results he achieved in a number of test cases submitted to him by Professor B. S. Schulze, of Jena, at that time the most prominent gynecologist of Europe, were so remarkable that physicians throughout Europe took notice and began using massage in a great variety of woman's ailments.

As often happens in the case of a new method of treatment that holds out great hope in heretofore seemingly intractable cases, so massage in gynecology was overdone and abused. The consequence was that many physicians failed to get the expected good results. Naturally, but unjustly, they blamed the method. They did not consider that the inherent difficulties in the proper application of massage, the lack of experience in selecting suitable cases, and the utter disregard of existing limitations could, possibly, lead to no other end.

Gradually, however, conditions settled. As the outcome of much discussion and a thorough study, the indications, contraindications, and limitations of pelvic massage became better known and are now well established. With increasing knowledge the number of successes also increased until today a great many European physicians are using massage of the female pelvic organs as a routine measure with most satisfactory results and recommend it highly.

In spite of this fact, there are many physicians of skill and knowledge who tried massage and failed even in properly selected cases. They are disappointed and discouraged and disparage pelvic massage as a therapeutic measure. Among these are physicians of prominence and recognized ability. Why have they failed where Thure Brandt and others succeeded? So far, there has not been advanced a satisfactory explanation to clear up the situation, though it would be of great practical value to know the reason.

The very fact that pelvic massage has won a permanent place in the treatment of diseases of women and is successfully practised by many physicians is sufficient proof that the method itself is not at fault. Massage is, indeed, recognized and acknowledged as one of our best palliative or curative measures for the very same afflictions for which it is recommended in women, if such afflictions are at the surface of the body or where they are easily accessible. Here as well as there it is used to remove remnants of inflammatory conditions, to improve local circulation, or to free nerves, bloodvessels, or organs imbedded in, or distorted and displaced by cicatricial tissues, and has proved equally satisfactory in both instances.

If the method is not at fault, we must, of necessity, look to the physician for the cause of failure. With him, in fact, the trouble lies. It is due to the special requirements demanded of the operator. General massage requires comparatively little medical knowledge and skill and no special fitness, save physical strength and endurance. Pelvic massage, on the contrary, requires a high degree of knowledge and skill, but, above all, fingers sufficiently long to render the pelvic organs readily accessible to the masseur. It is this last mentioned requirement which has not received the attention it deserves as an absolute prerequisite to success in pelvic massage.

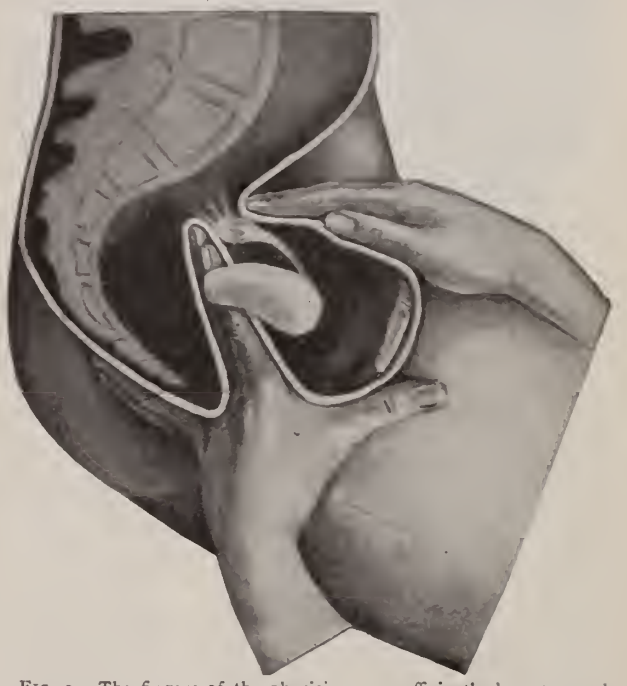

Fig. 1.—The fingers of the physician are sufficiently long to reach behind the ovary. In pressing the outer and inner fingers together, the ovary slips forward and the adhesions become accessible. They can now be stretched or broken, as the case may be, and the patient relieved.

Nothing is more obvious than that success in this important branch of the medical healing art must depend, first of all, on the ability of the physician to get freely to the organs from all sides. If he cannot thoroughly reach them, he, certainly, cannot successfully treat them. Let us assume that the doctor masters his anatomy, that he has sufficient experience and skill in examining women to enable him to outline clearly and definitely the pelvic organs and

to make a good diagnosis, that he knows his pathology and the indications and contraindications of pelvic massage, and that he is fully competent to select the proper cases and to reject those not suitable for this kind of treatment. Such a doctor has all the qualifications to be, or to become an excellent gynecologist, or gynecological surgeon, but he will not be successful in pelvic massage if the length of his fingers falls below a certain measure. For a better understanding I refer to figures 1 and 2.

There are many other conditions beside that illustrated with which short fingers are not able to cope. Every sixteenth of an inch more or less means just so much more or less toward success or failure in treating women by massage.

Fig. 2.—The fingers of the physician are not long enough to reach behind the ovary, though he may feel it and ascertain its site, size, contour, tenderness, and all other normal or abnormal conditions. In pressing the outer and inner fingers together the ovary slips backward and the adhesions become inaccessible. They cannot now be treated by massage, and the patient cannot be relieved, in spite of the fact that the physician may make a good diagnosis and knows well what should be done.

The varying length of the fingers of the different physicians will alone explain much of the perplexing difference of opinion apparent in the literature on pelvic massage. Other things being equal, the physician with long fingers will work easily, quickly, and without causing much pain. He is the one who succeeds and recommends massage. The physician with short fingers, however, will work under stress and difficulties and cause much pain. He is the one who fails, loses his patients, and decries massage. An investigation of the comparative length of the fingers of those for and against massage will, I am convinced, fully bear out this statement. My personal observations have been most convincing. Of course, radical surgeons, who have never tried massage, and who give consideration to nothing but surgical methods in the treatment of women, are not included in this estimate.

To provide for some more definite figures as to the length of fingers necessary for pelvic massage, I may state that the available length of my own middle finger is three and fifteen sixteenths inches. This is decidedly more than the average length, as confirmed by my personal observation. In spite of this decided advantage, I have occasionally realized that still longer fingers would give me even quicker and better results. Dr. Robert Ziegenspeck, of Munich, Germany, one of Europe's most ardent and successful advocates of pelvic massage, has fingers slightly longer than mine. He studied under Thure Brandt personally and had ample opportunity to observe the length of the fingers of this master. While I was assistant at his clinic, I heard Ziegenspeck remark a number of times that his—that is, Ziegenspeck's—fingers were midgets compared to those of Thure Brandt. Many times since I wondered how much of Thure Brandt's extraordinary success was due to the extraordinary length of his fingers and how much to his undoubted genius.

These disclosures are of no small moment from a practical standpoint. There is a large percentage of gynecological cases that can be successfully treated in no other way than by massage. I refer here to women with postoperative pelvic adhesions, if a second operation is out of question, and to those far more numerous women who are afflicted with chronic shrinking processes within the ligaments and their many distressing symptoms. Then there is a still larger percentage of cases for which pelvic massage constitutes not the only, yet the best and most successful treatment. If we would do justice to these cases, we must train physicians in pelvic massage in postgraduate schools. But pelvic massage is not easy. To avoid disappointment to physician and public alike, it remains essential to select from the applicants for tuition only those who have the proper physical as well as scientific qualifications, as has been explained.

30 North Michigan Boulevard.

INFLAMMATION WITH REGARD TO ITS STAGE.*

The Necessity of Treating It,

By John F. X. Jones, M D.,
Philadelphia,
Surgeon, St. Joseph's Hospital.

I neither hope to revolutionize ideas about a subject so well known as inflammation nor shall I apologize for what may seem a return to first principles. The eagerness with which many in our profession have seized upon dogmatic formulæ in methods of treatment, has influenced me to the belief that pathological conditions are too often disregarded in the treatment of inflammation. I can no longer ignore the fact that, often, both in hospital and in private practice, stitches are removed after a certain number of days, not because their usefulness has ceased, but solely because Doctor So-and-so holds that on the seventh, eighth or what-not day all stitches should be removed. Irritatingly frequent are the instances of drainage tubes being removed from gallbladders, regardless of the bacteriological

*Read at Pottsville, Pa., before the Schuylkill County Medical Society, May 2, 1916.

report on the bile. Why? Because Professor So-and-so states that on a certain day drainage must cease, and if it does not cease upon this sacred day, the drainage is not only harmful to the gallbladder, but personally offensive to Professor So-and-so. In like manner, cold or heat is often applied to an inflamed area regardless of the stage of the process because of the *ipse dixit* of some alleged authority. In other words, some of the members of our profession, when confronted with the problem of treating inflammation, instead of reasoning, What are the pathological changes in this tissue, say to themselves, How would Doctor X. treat this case?

Facts are always facts, eternal and immutable, whether our knowledge of them be obtained in the laboratory or at the bedside. Whether our investigations are conducted upon rabbits and guineapigs or upon men and women, inflammation is always a definite process, consisting of certain stages. Define it as we will, inflammation essentially is, as Adami says, the response of tissue to injury. We may accept the definition of Sir John Burdon-Sanderson, who says that inflammation is "the succession of changes which occur in a living tissue when it is injured, provided that the injury is not of such a degree as at once to destroy its structure and vitality." We may concur in the belief of Adami that inflammation is "the series of changes constituting the local manifestation of the attempt at repair of actual or referred injury, or, briefly, the local attempt at repair of actual or referred injury;" the fact remains that inflammation is a mobilization against an attack on tissue.

Be the attacking force traumatic, chemical, malignant, thermal, actinic, or bacterial, the first act of Nature is to order active hyperemia to the region assaulted. Here capillaries, venules, and arterioles dilate and the blood current becomes more rapid with consequent increase in the quantity of *moving* blood in the inflamed area. We are now considering a real attack, as there may be no vascular dilatation after a trivial aggression, or, a slight irritation may even cause arterial contraction because of nerve stimulation. When, however, the assault on tissue is severe or sustained, active hyperemia is the first line of defense and the locality of the conflict looks red and feels hot. Here the action may terminate by active hyperemia completely driving off the invading irritant, or the battle continues for a variable time, when retardation takes a hand. The blood current now grows slower and slower in the venules, capillaries, and arterioles, the red cells occupying the axial current and the white cells lining the venule walls. The white cells are now seeking an opportunity to migrate into the perivascular tissue. Eventually the liquor sanguinis and the white corpuscles travel through the walls of the veins and capillaries, the red cells congregate in masses within these vessels, and if the affair goes on to stasis there is clotting of the remaining intravascular material. The perivascular tissue cells are phagocytes and, when irritated, enlarge and reproduce while the exuded liquor sanguinis clots. These cells multiply or die, depending upon the gravity of the invasion; or, the centre of a mass of perivascular cells may be killed off, while the periphery is multiplying. The result of connective tissue reproduction is the fibroblast, which forms fibrous tissue and disposes of the leucocyte.

If we now return to an earlier stage of the conflict and follow the fortunes of a valorous leucocyte, we find that, after he has penetrated the vessel wall, he joins the other members of his army corps in an attempt to surround and halt the invader. He may even penetrate into the enemy's lines and engage a bacterium in single combat. He may make a prisoner of a microorganism or pick up a fallen comrade in the shape of tissue débris; in either case he retires to the rear, away from the line of conflict. He may die on the battle field, in which event he quickly decomposes, while from his remains is liberated fibrin ferment which coagulates exudate. Should he escape this latter fate, his country, the tissue, will show its appreciation of his patriotic services by having him eaten up by a fibroblast.

That power which impels the white cells to the scene of the inflammation is called by the pathologist "positive chemotaxis" and, unfortunately, there are a few instances where the invading bacteria are so virulent that "negative chemotaxis" influences the leucocytes to fly from the inflammation. Usually, however, inflammation draws legions upon legions of leucocytes to the affected area, and each leucocyte not only possesses the ability to approach and encompass bacteria, but also furnishes enzymes highly destructive to the poisonous products of these microorganisms. In addition to this local manifestation, many inflammations cause a general leucocytosis.

Inflammation, then, no matter how defined, no matter where located, no matter how caused, is the resistance of Nature to an attack on tissue. Any treatment not based upon a conception of these tissue changes must be haphazard and utterly unworthy of the conscientious practitioner.

It is scarcely necessary to say that the first step to take in the treatment of inflammation is to remove, if possible, the exciting cause. I say "if possible" advisedly, because it might be extremely difficult, if not utterly impossible, to remove the exciting cause —the exciting cause of a black eye, for instance. The exciting cause, whether it be a splinter in the hand, a stone in the bladder, a bullet in the leg, bacteria in the tissue, or any of one thousand and other agents, is, if possible, removed promptly. This cause having been removed the further treatment is local and constitutional.

Two of the most important means of treating acute inflammation are rest and elevation. These means are applicable in all stages of the process. Nature gives us the cue to treat inflammation by rest when she causes muscular rigidity in the neighborhood of inflammation, in order to rest the inflamed part. Rest tranquilizes the circulation, lessens tension, and hence, pain; regulates the quantity of blood to the inflamed area; and prevents the dissemination of infection by allowing the leucocytes to form a circle around the diseased area. There is scarcely any exception to the rule of rest in the treatment of acute inflammation. The surgeon deflects the course of the stomach contents by gastroenterostomy in order to rest a pyloric or duodenal ulcer. Cholecystostomy

is performed that the gallbladder, its ducts, or the pancreas, may have rest. A renal calculus is removed in order to rest the kidney; a stone in the bladder is removed to rest this organ. The chest is strapped in pleuritis to limit respiration on that side. An inflamed joint is splinted, extended, and perhaps placed in plaster, in order to secure rest. Splints are applied in fractures until Nature manufactures callus. Colostomy affords rest to the rectum invaded by malignant disease. Catheterization rests the bladder. Herniotomy gives rest to the structures constricted by the ring. Relaxation affords rest to inflamed muscles. Opium rests the inflamed bowel. The partial or complete exclusion of light from the eye is resorted to by the ophthalmologist in order to quiet inflammation.

With elevation we attempt to reestablish normal equilibrium in the circulation. When there is inflammation in the upper or lower extremities we raise the part. Who does not know that a toothache is aggravated by the recumbent position? We have all noticed the relief that elevation of the hand gives to the possessor of a felon.

In the first few hours of inflammation, when there are engorgement, high tension, and beginning effusion, local bleeding and the application of cold are valuable agents. In this stage, it matters little whether we bleed locally by means of puncture, leech, incision, or cut; but cold, except in the first few hours of inflammation, is positively harmful and certainly should never be used in the presence of infection.

Heat is rarely employed in the first stage of inflammation, because an amount of heat sufficient to contract vessels is usually very uncomfortable to the patient, even if it falls short of destroying tissue.

When inflammation is at its height and swelling is greatest because of effusion and proliferating cells, we are obliged to induce absorption, and for this purpose use such agents as astringents, sorbefacients, the douche, gentle massage, heat, and compression. While it is true that astringents may be beneficial in skin inflammations (certainly, lead water and laudanum give relief in erysipelas), it is open to debate whether these agents exert any influence upon deep seated inflammations.

This is as opportune a moment as any to discuss the much abused lead water and laudanum solution. Lead water and laudanum are used in the early state of inflammation as an evaporating solution to produce cold. Then why, when used in this stage to produce cold, is it so frequently covered up with wax paper, oiled silk, or rubber dam? These impervious materials, placed over the lint or gauze saturated with the solution, certainly prevent evaporation, inhibit the production of cold, and therefore defeat the purpose for which this lotion is employed. Again, if lead water and laudanum are used in the stage of stasis wherein cold is contraindicated, the lotion then *should* be covered by waxed paper, oiled silk, or rubber dam. The value of its use in the later stages of inflammation is questionable, but still, if it is used in these stages, it certainly should not be employed to produce cold where cold is contraindicated.

Saturated water solution of magnesium sulphate, especially valuable in orchitis; tincture of iodine, the astringent, sorbefacient, counterirritant, and germicide; nitrate of silver, useful in the treatment of mucous membranes; blue ointment, a splendid application over joints, tendons, glands, and bone inflammations; and the ubiquitous though odoriferous ichthyol—all have their merits and advocates and certainly play important roles in the drama of inflammation. These valuable remedies it would be a waste of time to dwell upon.

There is, however, one agent which we all use in the treatment of inflammation; a simple, mechanical means to which we all resort; an efficient remedy when properly used; a terrible force for evil when ignorantly applied—I refer to compression. When we apply compression to the inflamed part, by means of either the bandage or adhesive plaster, the additional support thus furnished to the bloodvessels and lymphatics causes them more readily to imbibe the effusion and in this manner to hasten absorption. We bandage the extremity afflicted with erysipelas, strap or bandage the leg ulcer, and bandage the joint which is the seat of chronic inflammation. In fracture the bandage controls spasm, reduces swelling, and relieves pain. If, however, the compression is applied with force a simple inflammation may be changed into a hideous gangrene. If we apply a firm bandage to the forearm and arm without including the hand, the latter is liable to become the seat of painful edema; if we compress the leg firmly without including the foot, painful swelling of the foot may result. The ends of fingers and toes, where possible, should be left exposed in order to observe circulatory changes. Fundamental as these rules may be, I have seen them disregarded frequently, and, occasionally, with results disastrous to the patient and embarrassing to the surgeon.

The douche, hot, cold, or alternatingly hot and cold, is frequently used in inflammation. If the inflammation is acute, the douche, unless extremely gentle, may cause great pain. Counterirritants alleviate pain early in inflammation and later hasten absorption. Massage is of great benefit in chronic inflammations, but must be used cautiously and lightly in any acute process. Never use massage where there is infection. Never use massage where there is thrombosis.

Upon the constitutional treatment of inflammation, a skilled therapeutist could speak for hours, but, fortunately, my limited knowledge of drugs will serve me to dispose of this part of the subject quite briefly. First and foremost, unless the bowels are already overacting, a purge should be given. This is a mere matter of plumbing. Before stasis has begun, some arterial sedative, such as aconite, may be administered; if given after stasis has been established, the arterial sedative will, of course, increase the stasis. Diaphoretics, such as Dover's powder, given at the beginning of the process, will remove toxic material and may curtail the inflammation. When the urine is scanty and high in color, diuretics, such as large doses of calomel and black coffee, may be given. Of course, anodynes and hypnotics may be necessary to relieve pain and induce sleep. Later, mercury and the iodides may be used in the removal of the products of inflammation. At any stage of inflammation a stimulant may be required; and, during convalescence, a tonic.

Coaltar derivatives, used solely for the purpose of

lowering temperature, are, in my estimation, dangerous. Fever being the state in which the patient is burning up and making toxic elements within him harmless, why discourage his elevated temperature with antipyretics? Unless the high temperature is accompanied with nervous symptoms, it seems to me to be good practice to leave it alone.

There are times in inflammation when the old fashioned treatment of general bloodletting may be employed with great benefit. General bloodletting corrects stasis. If the patient is in his "youth, the glad season of life," if he is vigorous and strong, the inflammation acute, and the location involved vital, he may be bled to advantage during the first stage of the process. If, on the other hand, the patient is aged, feeble, and frail, the inflammation low, and the part affected unimportant, he should not be bled under any circumstances. Bleeding should never be resorted to in the later stages of inflammation or in cases where the face is pallid and the pulse compressible, soft, irregular, small, and slow. We should bleed when the patient's face is flushed and when his pulse is rapid, hard, full, and incompressible. Phlebotomy should never be performed upon a drunkard, a fat patient, a very nervous subject, or a victim of an epidemic, septic, or adynamic disease.

No discussion upon the subject of the treatment of inflammation can be conducted without reference to that extremely valuable method invented by Bier. As we know, Bier considered hyperemia a blessing in that it does away with the irritant causing the inflammation and brings nourishment, phagocytes, and bactericidal liquor sanguinis to the affected part. Stasis, on the contrary, reduces the resistance of tissue and may result in gangrene. By means of the rubber band and cupping glass, Bier induces venous hyperemia, and arterial hyperemia he produces by means of hot air. This method is useful in either acute or chronic inflammation.

These, briefly, are the more important agents used in the treatment of inflammation. In the preparation of this article I have followed, in the main, Dr. J. Chalmers Da Costa's chapter on inflammation in his *Modern Surgery;* for his permission to do so, as well as for his kindly criticism of this paper, I am deeply grateful.

Now the old question arises: "When shall we substitute cold for heat?" It is true that some surgeons employ heat in the earliest stage of inflammation, but, unless it is in the management of an inflamed joint by the hot air apparatus, heat is not to be recommended in the beginning of inflammation. In the first stage of inflammation the indication is to contract the vessels and, as has been stated, any temperature sufficiently high to cause this contraction is bound to be uncomfortable. We use cold, then, in the beginning of an inflammation and continue it certainly not longer than a few hours. We use cold before retardation has begun because we hope, by decreasing the amount of blood to the part, to prevent the process from reaching the stage of stasis. Now, if the process has already arrived at the stage of stasis when we see the patient, what is the sense in using cold? In stasis our purpose is to activate the stagnant or slowly moving blood, cause the exudation to be drunk up, stimulate lymph absorption, decrease tension, bring hordes of leucocytes to the part, and increase the ameboid activity of these leucocytes. All of these indications are met by a moderate degree of heat. Skin inflammations, of course, are not governed by these rules because most cutaneous inflammations are made worse when congestion is increased by heat.

Heat as an agent in the treatment of inflammation is more fool proof than cold. To begin with, cold in the only stage in which it should be used, the stage of active hyperemia, must be used continuously, because, if employed intermittently, there follows a reaction, and every time the cold producing agent is removed, this reaction will increase the hyperemia which we are striving to lessen. Now, if cold is used continuously, even in the active stage of hyperemia, there is danger of gangrene. This danger is particularly imminent if cold is applied to an old or feeble patient.

Why should cold never be used after the stage of retardation has begun? Because, in this stage, we wish all the leucocytes possible to migrate to the inflamed area. Heat brings leucocytes to the part. Cold drives them away. Because we wish to have *active* leucocytes. Heat increases ameboid activity, and cold prevents it. Because, in this stage, cell proliferation is eminently desirable. Heat increases cell proliferation, and cold retards it.

Where there is a bacterial inflammation cold should *never* be used, because, by keeping leucocytes away from the infected part, cold actually spreads the infection. Heat favors the formation of a protective barrier about the infected area, while cold prevents the tissues from defending themselves.

The fact that many surgeons apply ice bags to the abdomen in suspected appendicitis does not make this practice a logical one. In the first few hours of an attack of appendicitis, when the ice bag might be of use, the diagnosis has seldom been made, and the ice bag decreases pain and lessens rigidity almost as effectively as a dose of morphine. Hence the ice bag interferes with the diagnosis. Seldom, however, does the surgeon see appendicitis during the short stage of hyperemia. When the surgeon is called to see the case, there is more or less stasis. The ice bag increases this stasis, prevents the arrival of leucocytes, discourages the production of adhesions; in short, weakens resistance. I am convinced that the ice bag gravely increases the risk of gangrene. I have seen gangrene in the abdominal wall follow the prolonged application of the ice bag in appendicitis.

Inflammation must be treated with due appreciation of its stages, if it is to be treated intelligently. It is better to leave an inflammation alone if we do not handle it with due deference to its stage. Nature, if unhampered, may cure inflammation occasionally, but how can she accomplish anything if interfered with by one who defies pathology and repudiates his own experience.

Inflammation, as a subject for discussion, is old and trite. Thousands upon thousands of guineapigs, rabbits, dogs, frogs, pigeons, and other animals have been immolated upon the altar of the great god, Science, by the zealot who would penetrate into its sacred mysteries. Untold volumes (some unread) have been written throughout the universe by the patient pathologist who would initiate the eager neo-

phyte into its rites. If, then, a plain, ordinary surgeon does not apologize for bringing such an antiquity here, it is because Agnew said that "During the year 1874, in the city of Philadelphia there was a total mortality, exclusive of stillborn children, of 15,424, of which number not less than 11,000 may be fairly attributed directly or indirectly to inflammatory complications"; and, while after forty-two years the number of deaths is naturally greater, the proportion of deaths traceable to inflammatory causes remains about the same.

1815 Spruce Street.

RECTAL OPERATIONS UNDER LOCAL ANESTHESIA.*

By J. F. Saphir, M. D.,
New York,
Assistant Surgeon, Rectal Department, O. P. D., Gouverneur Hospital; Visiting Surgeon, Diseases of the Rectum and Anus, People's Hospital, etc.

It affords me great pleasure to describe a number of patients representing a series of interesting rectal cases operated in at the Gouverneur Hospital under local anesthesia. All of these patients presented either transient cases, such as would ordinarily come into one's office unprepared for operation but requiring one, or individuals who had been sent to the clinic or hospital to be admitted for operation. All of these cases, under the local influence of quinine and urea hydrochloride solution, were relieved of their rectal ailments, feeling no inconvenience either during or after operation, and left the clinic immediately, each one to attend his or her regular duties or occupation the same day or the day after operation.

These cases are interesting for many reasons:

1. It proves that rectal conditions can be cured under the influence of local anesthesia.

2. The patients need not be confined to bed, and can go about their business immediately after the operation or the next day.

3. It proves that rectal operations can be performed in the clinic, or for private patients at the doctor's office.

4. The consent of many patients who require rectal operations, but who fear the word "hospital," and shrink at the idea of being put to sleep under a general anesthetic, can be obtained when they are convinced that they can be operated on under a local anesthetic without pain.

5. Patients suffering with pulmonary tuberculous, nephritic, or cardiac diseases can with safety be operated on under the influence of a local anesthetic.

6. Many patients cannot afford to be confined in a hospital or at home for ten days or two weeks or more, as is customary in operations on the rectum under a general anesthetic.

The business or society man often cannot neglect or give up his business or social duties for two weeks or more, for the sake of having his rectum looked after. Working along the line of least resistance, he falls into the hands of quacks through their skillfully worded advertisements, or resorts to the use of salves, lotions, powders, or suppositories, and often neglects going to his doctor for a rectal examination, for fear that an operation may be necessary.

7. From an economic point of view, especially for the hospital and for the city, rectal operations under local anesthesia prove to be a great saving.

The patients whose histories I present show what has been accomplished during the two months that this clinic has been in operation. Out of sixty-five new patients, fifty were operated on in the clinic under local anesthesia, who ordinarily would have been admitted to the hospital, would have occupied beds, each for a period of ten days or two weeks; this means a saving to the city of about one hundred weeks of food and medication during a period of two months; at the same time it relieves the congestion of the hospital, especially at this busy season of the year and makes room for the admission of more urgent cases.

Rectal cases in a general hospital have always been looked upon as minor surgical cases, of little importance, so much so, that the general surgeon on getting a rectal case, would usually hand it over to one of the house staff for operation. The house surgeon, owing to the inefficient amount of teaching or stress laid upon rectal conditions at the undergraduate school from which he was sent forth to practise the art of medicine and surgery, usually does the best he can; follows the description in his textbook, and discharging the patient after two weeks or more, is much surprised when the patient returns with the same complaint that he had before he was operated upon.

I have come across cases where the surgeon when told by his patient that he had what he termed "bleeding piles," took the patient's word for it, and without bothering about making a rectal examination, removed a few small bits of mucous membrane under a general anesthetic, kept the patient in the hospital for two weeks, and was surprised that that patient still had blood in his stools; and he was more surprised when by means of a proctoscopic examination, he had ample proof that that patient never had "bleeding piles" or any other kind of piles, but was suffering with a coloproctitis with ulceration.

I have had referred to me, a young girl of nineteen years, whose case was diagnosed as "bleeding piles," and which on examination proved to be a small round celled sarcoma of the rectum. I can report rectal abscesses kept in the hospital for two weeks, and all that was done was incision and drainage; when the patients left the hospital, the abscesses were still discharging pus, causing excoriation and itching and making the patient's life unbearable. Either a complete operation could have been done at the time of the first operation, or the patient might have been advised of the necessity of an operation for fistula at a future date.

These patients come to the clinic for relief every day, and I shall describe a number of them, who after having had two sessions and two operations at good institutions, were finally operated on at the clinic under local anesthesia, and were cured.

I do not wish to be misunderstood; I do not con-

*Presented at the Surgical Conference of the Clinical Society, Gouverneur Hospital, January 21, 1916.

denn hospitals or surgeons, but I wish to emphasize the importance of more frequent rectal examinations by the general practitioner as well as by surgeons and interns at the hospitals. I remember an interesting patient who was operated on for appendicitis at one of our largest hospitals; the complaint was bleeding at stool for the past one and a half year, a loss of twenty-eight pounds during that time, and pain in the lower half of the abdomen; and even in this case no rectal examination was made, although the woman was suffering with a distinct growth in the rectum reaching from one inch above the anal opening and involving the sigmoid, with an annular stricture which would not admit even the tip of the little finger.

I wish to emphasize the necessity for more extensive teaching of rectal diseases in the undergraduate schools and colleges. I wish to emphasize the importance of sending out graduates of medical colleges who are able to cope with diseases and ailments of every day occurrence as well as with those of rare and infrequent occurrence. I wish to emphasize the importance of the establishment of a rectal department in every hospital and in every dispensary, as well as rectal teaching in every medical school and hospital.

Some of our best doctors still clip off the "sentinel pile" in a case of fissure ani, and feel that they are doing the right thing, and yet are surprised when the patient's sufferings are aggravated instead of relieved. Many physicians still grasp a thrombotic hemorrhoid and either ligate it or remove by Paquelin cautery, when all that is necessary is to incise and turn out the clot. Many are the patients whose ani and whose buttocks are daily painted with twenty-five per cent. or fifty per cent. silver nitrate solution for itching, by doctors who look upon pruritus as a disease rather than a symptom, when the patient is suffering with pin worms, or a proctitis with or without ulceration, or a blind internal fistula, or a polyp or hypertrophied papillæ, or internal or external hemorrhoids, when all that is necessary is the relief of the condition higher up which is causing the moisture or discharge, and hence the pruritus.

How many patients complaining of blood in their stools, and a feeling of fullness and discomfort in the rectum, are treated with salves and suppositories, are either purged with violent cathartics, or "doped" with opiates, are found later to have been suffering with some malignant growth, and neglected only because the doctor either did not insist upon a rectal examination or was afraid to soil his finger, or merely took the patient's word. To the lay mind, any trouble or inconvenience about the rectum, is looked upon as "piles," "open" or "closed" or "bleeding," and often physicians of good repute follow in the tracks of their patients, and make similar diagnoses. They are not to blame, for at the medical school from which they graduated, they were taught to look upon rectal diseases as piles, fistula, fissure, or abscess.

Case I. Mr. R., aged sixty-seven years, a rabbi, suffering for fifteen years with protrusions from the rectum, and blood with and after stool, a fullness in the rectum and pain after stool, moisture and itching, who had been going the rounds among several doctors, who had given him salves and suppositories without relief, came to the clinic, and was found to be suffering with prolapsed and ulcerated internal hemorrhoids, polyp, and skin tags. Under the influence of quinine and urea hydrochloride 0.5 per cent. solution, as a local anesthetic, he was operated on; the prolapsed and ulcerated internal hemorrhoids and polyp were removed by ligature operation, and the skin tags were snipped off. Pressure was applied by means of a tight sterile dressing and T binder; the patient left the clinic, having had no pain either during or after the operation, attended to his vocation as before the operation, and came back every clinic day for aftertreatment. He felt well subsequently.

Case II. Mr. L., aged thirty-six years, driver, was operated on twenty months ago at one of the large city hospitals for "piles," was in the hospital ten days, and again noticed the same trouble, also has noticed protrusions and itching. Examination revealed pruritus ani due to pin worms as well as skin tags. With a 0.5 per cent solution of quinine and urea hydrochloride as a local anesthetic, he was operated on at the clinic; his skin tags were removed. Saline irrigations were ordered twice a day for the pin worms. He had no pain during or after the operation, walked home, attended to his work, and came to the clinic every other day for aftertreatment.

Case III. Mr. K., aged twenty years, noted a swelling about the anus three weeks ago, was operated on at one of our city hospitals, evidently for an abscess, was kept in the hospital for two weeks, and since his discharge, complained of a swelling, discharge of pus, and moisture. Examination revealed a perianal fistula due to a dermoid cyst. Under local anesthesia of quinine and urea hydrochloride, we incised the wound, opened up the fistulous tract, curetted, removed a bunch of encysted hair, and after proper drainage the patient was discharged, cured, after three weeks. He had no pain during or after operation, and was not kept from his work during the entire course of treatment.

Case IV. Mr. K., aged thirty-nine years, has been complaining of pain, protrusions, and bleeding with stool for the past year, during which time he had been using salves and suppositories without relief. About one week ago, after straining at stool, he noticed a large protrusion, which was hard and painful, and which he could not return. Pain was continuous, and especially severe on sitting and on walking. On examination it was discovered that he was suffering from external and internal hemorrhoids and also a thrombotic hemorrhoid. He also was operated on under quinine and urea hydrochloride solution, felt no pain during or after operation, attended to his work the following day, and called at the clinic for aftertreatment.

Case V. Mr. S., aged thirty-one years, newspaper man, had an abscess in the rectum about ten weeks ago, when he was operated on at one of our large hospitals, was kept there for ten days, but still had a discharge. About five weeks ago, he again noticed a swelling at the same place, and his doctor opened the swelling and relieved him of the pus. He had been having a discharge ever since. Examination showed that he had a fistula due to an ischiorectal abscess. He was operated on under quinine and urea in the clinic, felt no pain during or after the operation, and felt well afterward.

Case VI. Mr. G., aged forty-six years, tailor, felt well until two months ago, when he noticed moisture and blood with stool, and itching, but no protrusions. Examination revealed a blind internal fistula, which was operated on in the same way as the previous cases with the same results.

Case VII. Mr. L., aged sixty-one years, complained of bleeding in the stools for the past eight years. Had diarrhea for six weeks, had fifteen to twenty movements a day with a discharge of mucus, pus, and blood; had protrusions which could not be returned for the past week and which stayed out all the time; he had pain on sitting and on walking, and had lost weight. Upon examination, we discovered external and internal prolapsed and ulcerated hemorrhoids, as well as a coloproctitis with ulceration, also a thrombotic hemorrhoid. He was operated on under local anesthesia for the hemorrhoidal condition. And for coloproctitis, he was given cold starch irrigations in conjunction with irrigations of krameria solution, and internally, strychnine grain one thirtieth three times a day to tone up the muscular coats of the wall of the rectum. He soon felt well, gained in weight, had no blood or pus or mucus discharge from his rectum, had but one movement a day, and was again a fit member of society.

Case VIII. Mr. R., aged thirty-nine years, had been complaining of severe pain and protrusions for the past four years. Since then he had been operated on four times, the first time about four years ago. He now complained of burning, itching, continuous discharge and moisture, and a small protrusion. He passed no blood and was constipated. Examination showed a blind internal fistula, which we operated on under quinine and urea hydrochloride.

Case IX. Mr. DeP., aged twenty-five years, was well until four days ago, when after a difficult movement, he noticed a protrusion which was hard and painful, remained outside, and could not be returned; no blood, but severe pain on sitting and on walking. Examination showed a thrombotic hemorrhoid, which under quinine and urea hydrochloride was incised, the clot turned out. The edges of the wound were trimmed for proper drainage, a strip of moist gauze was inserted, a dressing and T binder applied, and the patient went home without having experienced any pain during or after the operation.

Case X. Mr. H., aged forty-four years, was operated on four years ago and again two years ago at one of our leading hospitals for abscess and fistula, and came to the clinic for the relief of a very annoying discharge about the anus. Examination showed a fistula. This was operated on under local anesthesia, same as the preceding cases, and he was cured of his fistula and had no inconvenience during or since the operation.

Case XI. Mr. C., aged sixty-two years, came to the clinic with external and internal hemorrhoids, from which he had been suffering for the past fifteen years, and without pain during or after the operation, was relieved of his condition under quinine and urea.

Case XII. Mr. K., aged thirty-six years, complained of pain, protrusions, and blood with stool. Was operated on four years ago at one of our city hospitals, where he was kept for two weeks; two years ago, he noticed a swelling at the same spot. He applied salves and hot applications, the swelling opened and discharged a quantity of pus and blood; he felt well except for a discharge until two weeks ago, when another swelling formed, which was painful on sitting, standing, and walking. He again entered the same hospital, where he was operated on and was discharged two days ago, when he came to the clinic for aftertreatment. On examination we found two canals connecting and discharging pus, which would have prevented healing and would in all probability have been the nucleus for a fistula and abscess formation at some future date. Under local anesthesia, we opened up these two tracts, and with proper drainage, effected a cure.

Case XIII. Mrs. T., aged twenty-eight years, felt well until four months ago, when after a hard stool she noticed first a burning then severe pain after stool, lasting almost all day; also noticed occasional blood after stool and a small protrusion. She was constipated and took cathartics. Had felt worse for the past two months. She complained of steady and continuous pain, especially after stool. Examination revealed a fissure ani in the posterior anal margin, with two long sentinel piles or skin tags. Under quinine and urea the sphincter muscle was cut to relieve the spasmodic contractions, the skin tags were removed, and she had comfortable movements afterward. She suffered no pain during or after the operation.

Case XIV. Mrs. F., aged thirty-five years, had been suffering for the past fourteen years with hemorrhoids, since her first baby was born. She now complained of protrusions and severe pain, especially after stool. She was afraid to go to stool for fear of the pain; she also noticed occasional blood on the paper after stool. Examination showed a fissure and a skin tag. This case was operated in like the preceding cases, with equally good results.

Case XV. Mrs. H., aged forty-three years, complained of "piles" for the past eighteen years, had noticed blood after stool, also had a protrusion which remained out all the time; she complained of pain on sitting and on walking, especially severe after stool, lasting about five or six hours. This case also was a case of fissure and skin tag, which was operated in like the previous case.

Case XVI. Mr. B., aged forty-nine years, had been complaining for the past six years of protrusions, moisture, and itching; his clothes were wet all the time, and he noticed blood on his clothes occasionally. Examination revealed prolapsed and ulcerated external and internal hemorrhoids and a polyp, which were operated on under local anesthesia.

Case XVII. Mr. F., aged forty-seven years, noticed bleeding with stools for the past two years; he had occasional itching and was constipated, had to take cathartics; he had protrusions, which returned by themselves after defecation. Examination showed external and internal ulcerated hemorrhoids, which were operated in under local anesthesia.

Case XVIII. Mr. G., aged forty-three years, was operated on at one of our city hospitals about one and a half year ago for "piles"; he felt well until three weeks ago, when he noticed severe pain in the rectum and some protrusions; pain chiefly accompanying defecation, no blood, no pus, no mucus. Examination showed external and internal hemorrhoids, which were operated on as in the previous cases, with equally gratifying results.

Case XIX. Mr. W., aged forty-five years, came to the clinic, holding a towel saturated with blood over his anus; he was stooping over, could hardly walk on account of the mass between his buttocks, and asserted that he was unable to walk or to work. He had been suffering with "piles" for the past five years, but this time they had come out and he could not return them. Examination showed a large mass of prolapsed and ulcerated internal and external hemorrhoids, the external hemorrhoids thrombosed, and the entire mass the size of a man's fist. Under quinine and urea hydrochloride solution 0.5 per cent., as a local anesthetic, he was operated on in the clinic, felt no pain during or after the operation, and went home, walking as comfortably as if he never had had rectal trouble.

I do not wish to be misunderstood, I do not hold that all rectal cases can or should be operated in under local anesthesia. There are some cases that need hospital care and treatment, but I do maintain that about seventy-five per cent. to eighty per cent. of hemorrhoids, external, internal, and thrombotic, rectal polypi, fissure ani, anal ulcers, dermoid cysts, tight or hypertrophied sphincter ani, skin tags, some cases of fistula ani, and some cases of prolapsus ani can and should be operated on under local anesthesia.[1]

237 West Seventy-fourth Street.

TREATMENT OF INEBRIATES.*

By Joseph McIver, M. D.,
Philadelphia.

INTRODUCTION.

Men have exhausted their skill, overdrawn on their imagination, and at times almost baffled the forces of nature in effort to find a specific cure for alcoholism. We have records to show that wine was used by the ancients even as far back as 5,000 B.C., and beer was drunk by the Egyptians. It would therefore appear that man has always craved something to drown his sorrows and to give him a sense of well being.

Alcohol has played an important part in the course of civilization. Its abuse has done a great deal of harm, but it is doubtful if its moderate use has injured any one, and as a therapeutic agent it has been of great value. As a political and sociological factor it has been of foremost importance.

Broadly speaking, alcoholism belongs to that great group of diseases known as intoxicants, for alcohol is a bacterial product. At times, alcohol may be

[1] During a period of seven months, or since the inception of a rectal department in Gouverneur Hospital, O. P. D., out of 176 rectal cases that presented themselves, 124 were benefited by rectal operation under local anesthesia with quinine and urea hydrochloride.

*Read before the Society for Organizing Charity of Philadelphia, April 11, 1916.

used in enormous quantities and for a long period without showing appreciable deleterious effects. We thus know that it may cause death acutely, or it may bring about widespread degeneration through years of excessive indulgence. Pathological, i. e., structural changes extend to all tissues except bone, but its effects are specially marked in the nervous system. Mental manifestations with alcoholism as a factor are numerous and any type of insanity may be simulated.

In order to consider this subject intelligently a few words about its causation and nature are indispensable.

Etiology. Almost since time began writers have tried to explain the causation of alcoholism. A host of theories have been advanced, but for our purposes the enumeration of the more important factors will suffice. Of these heredity and environment are foremost. It is an old adage that "drunkards beget drunkards," but of course almost anything may be proved by heredity. The influence of environment is so well known that it deserves no further comment. We are also familiar with such factors as the lack of education or improper education, incidental associations, etc. Of course, it must be remembered that one or more of these factors usually play a part in the cause. There are some whose fault may be attributed to one of these. There are others in whom it will require all to explain, and still others that will be difficult to explain on any basis.

The more we delve into this subject of the causation of alcoholism the more entangled we become. The problem is such a complex one and there are so many details to be considered, that a broad classification is necessary.

From the practical standpoint of treatment a few statistics collected from the Philadelphia General Hospital may be of interest.

During the year 1906 there were 12,141 admissions to the hospital, of which 1,061 were male alcoholics and 161 female alcoholics. There was a gradual increase in the total number admitted to the hospital with a corresponding increase in alcoholics, until 1915 there were 19,627 admitted, of which 2,279 were male alcoholics and 403 were female. Of course, these figures do not represent so many people, as many of them were admitted a number of times during the year.

In the past ten years there have been 155,041 admissions to the Philadelphia General Hospital, of which 25,830 were alcoholics, or approximately sixteen per cent. The proportion of male to female alcoholics varies from year to year, and has ranged from four to one to six to one.

Since the records of the male alcoholic ward for 1915 were the most complete, a somewhat detailed account of them is given.

The admissions by months ranged from 124 in February to 234 in December.

The average number of admissions that each patient has been accredited with during his lifetime was 8.1.

Six hundred and seventy-five were admitted for the first time, 225 for the second time, and 180 for the third. Some had been admitted a great many times—fifty-five, fifty-seven, sixty-two, sixty-three, seventy, seventy-six, eighty-eight, ninety-four, and 100 and more times.

The man who held the record with over 100 admissions has unfortunately landed in the insane department, where he will most likely spend the rest of his time. It will be interesting to know who his successor will be and what will become of him.

Of these patients 1,268 were single, 366 widowed, and 639 married.

The average age was forty-four years.

As to nationality, almost every part of the civilized world was represented—the majority, however, were natives of Philadelphia.

Philadelphia was the birthplace of 1,273; Ireland 381; Pennsylvania, outside Philadelphia, 197; New York 69; England 48; New Jersey 35; Maryland 29; Germany 26; Delaware and Virginia each 22; Scotland 18; Massachusetts 17; Canada 15; Connecticut 13; Ohio 12; District of Columbia 9; Illinois 8; Russia and Sweden each 7; Rhode Island 5; Italy, Austria, North Carolina, Arkansas, each 4; Minnesota, Kentucky, South Carolina, France, Cuba, each 3; New Hampshire, Hungary, Norway, Finnland, Poland, each 2; Colorado, Washington, Montana, Iowa, Missouri, Indiana, Texas, Mississippi, Nebraska, West Virginia, Wales, China, Denmark, Isle of Man, High Seas, each one.

The class of patients admitted to the alcoholic wards is variable, ranging from the lowest type of mentality on through the middle class, up to some who were once very bright men and women. Practically all vocations of life are represented, including clergymen, business men, bankers, brokers, druggists, lawyers, and physicians. The lower classes, however, make up the big proportion of the alcoholics.

TREATMENT OF INEBRIATES AT THE PHILADELPHIA GENERAL HOSPITAL.

At the Philadelphia General Hospital, alcoholic patients are admitted in the usual way. Some of them come in voluntarily; some of them are sent in by their friends, and a great many are brought in by the ambulance and police patrol. After admission they are sent to a special ward where they are confined to bed and receive treatment as the individual case demands. This method is continued and the patient remains in bed until he is well free from the acute toxic symptoms of alcohol. Some years ago a special provision was made whereby all alcoholic patients could be detained for thirty days after the first admission. When these patients are free from symptoms they are sent out to work around the institution. In this way they are kept under absolute restraint and control for one month. At the end of this time if the patient desires he may have his discharge. On the other hand, if he desires to stay longer he may do so providing there is room. The hospital authorities have been very lenient in this respect, allowing those who were really desirous of being cured to remain almost indefinitely and giving them every opportunity possible.

There are not a great many, however, who are anxious to stay longer than thirty days. These patients

are all anxious to have treatment to aid in the recovery from the acute symptoms of alcoholism, but not many are enthusiastic about remaining in the institution for any considerable time.

The attitude of these people as a class is against all that is necessary to remain free from alcohol. I might say that the living conditions at the hospital are far better than most of them are accustomed to in their every day life. Hence this, I think, could not be given as a reasonable excuse for their leaving; what they really want are liberty and whiskey. The hospital has gained something in the way of labor by holding these people for a month. This has likewise been somewhat beneficial to the patient by keeping him away from rum for a certain time. The community and city have been benefited. Apart from this, little has been accomplished. I do not believe the hospital would even think of laying claim to one single permanent cure out of all these thousands of cases. I have reference here to the chronic alcoholics. From my own personal observations I am sure that I cannot recall one, notwithstanding the fact that many of these cases had remained in the hospital for months or even years and had been brought into the best physical condition. As soon as opportunity presented itself, they became intoxicated. As just said, many of these people had been kept for months and some had been so faithful to their duties that they were placed on the payroll. Some would last for six months or a year, but usually one pay day was all that they could stand. They go on a spree until the money is gone and then back to Blockley to do another thirty days. And so the cycle keeps up until after a while the passageway through which the alcoholic enters and leaves the hospital becomes so smooth he can stay neither in nor out of the institution.

There are a great many who belong to this class who are commonly known as "old timers." The majority have spent the greater part of their lives between the House of Correction and the Philadelphia Hospital. They are working on a stone pile in Holmesburg one month and carrying a stretcher in Blockley the next.

CLASSIFICATION.

Broadly speaking, people who use alcohol may be placed in one of about three classes, namely: 1. The moderate drinker; 2, the excessive drinker; 3, the total inebriate. It is to the care and treatment of the inebriate that I wish to call attention.

PROGNOSIS.

Ordinarily, patients recover from an alcoholic debauch within a few days to a week's time. The various forms of mental disturbance and other complications always delay convalescence and many times render the outcome grave. As to the permanency of the results, a great deal depends upon the individual case. The whole thing is that the majority of these people do not care to stop using alcohol. There are some, however, who are really sincere in their efforts and they should not suffer on account of the insincerity of the greater number.

That there has been for many years a great demand for a rational, workable plan of caring for these perplexing cases every one will admit. That this demand is increasing day after day, and year after year, is evident.

The various so called specific cures have indeed been a great handicap, because they gave people a false sense of security. It was only natural that these so called cures would come out and be lauded by a great many, for the demand was so great. Many fell victims of these fake treatments and many of the promoters made immense sums of money. That many of these people suffered and paid dearly, I am sure, but as for the actual good they derived from the treatment I am somewhat doubtful. My own personal experience at the Philadelphia General Hospital would lead me to be somewhat skeptical regarding the very high percentage of permanent cures reported by some institutions devoted to the care of alcoholics. I am quite sure that there is no drug nor combination of drugs which will relieve the obsession for alcohol or opium.

TREATMENT.

To care for these patients only until the acute symptoms have subsided will only be a temporary aid. To expect to free them of the alcohol habit in a few days or a week's time is absolute folly and involves a useless expenditure of time and money. What they need is institutional care where they can be kept for months and years.

All subjects of inebriety should be removed from their present environment to an institution at least for a time. Here they should be kept under restraint and control until it is considered safe by the physician in charge for them to go.

An institution for the care of these cases should be situated, preferably, in the country. The buildings should be of modern structure with plenty of light and ventilation. The cottage plan is a very good one in order to make it as homelike as possible and at the same time permit proper classification of patients. A farm and industrial plant should be provided to afford employment for the inmates. By this means each inmate could be given work fitted to his or her ability. They should be thoroughly impressed with their weakness and taught that total abstinence from alcohol is the only course for them.

As to how long these patients should remain in the institution, a great deal depends on the individual case. I should say not less than three months for the mildest type, and some will have to be kept for a year or more, and it is doubtful if some would ever be safe in facing the outside world.

When these people leave the institution they should seek new associates and new surroundings. They should start life anew and engage themselves in some active work fitted to their ability, keeping ever in mind their weakness, at the same time remembering that anything short of total abstinence is sure to prove detrimental and will in all probability be the beginning of their downfall.

If we could only impress these people with the seriousness of their weakness and teach them how to live, the problem would be solved. Unfortunately this is extremely difficult and many cases, I am sure, are utterly hopeless.

The benefits to be derived from a plan of treat-

ment such as I have outlined are self evident. The difficulty lies in putting it into effect.

The value to the patient would be inestimable. He would be more than self supporting and become an aid to his family. The procreation of his kind would be largely prevented. From an economic standpoint, the help to the city and country at large would be marvelous.

The alcohol question will never be solved on a moral basis, but the time is coming when it will be solved and economy is going to be the main factor. The time will soon be at hand when industrial concerns will no longer employ alcoholics on account of the increased risk, and the whole thing will simply be a survival of the fittest.

CONCLUSIONS.

The main causative factors of alcoholism are heredity, environment, lack of education, and incidental association. A combination of these enters into most cases. For the past ten years sixteen per cent. of the patients admitted to the Philadelphia General Hospital were for the alcoholic wards. Practically all vocations of life were represented, but the lower classes made up the largest proportion.

The statistics before given would lead one to be somewhat skeptical regarding the very high proportion of permanent cures reported by some institutions devoted to the care and treatment of alcoholics.

I am quite sure that there is no drug nor combination of drugs which will relieve the obsession for alcohol or opium.

Institutional care with absolute restraint and control for an indefinite time seems to be the most rational plan of treating inebriates.

Broad and Arch Streets.

ACUTE MIDDLE EAR SUPPURATION.*

Some of Its Complications.

By John J. O'Brien, M. D.,
Schenectady, N. Y.

Last winter and this, mainly as a complication of grippe, there were many cases of middle ear infection, most of them going on to suppuration. The onset was nearly always ushered in with intense pain, but in some patients this was conspicuous by its absence. It might be well in about all cases of illness, except where the symptoms are definite, to examine the ear drums. For rapid inspection an electric otoscope is excellent. If the examination takes more than a minute or two, it would certainly be neglected by the man who makes a dozen or more calls a day. The information obtained in a few moments will inform and help in diagnosis and a more effective therapeusis. It is well to keep in mind that any ear may have been the seat of prior inflammation resulting in a modification of the anatomical picture; but after repeated use of the otoscope it becomes fairly easy to determine the present from the past. Great stress is laid, by teachers, on the bulging of the tympanic membrane as an indication for incision. There are many cases where there is no apparent bulging with resulting error if a free incision is not made. This too yields to practice, and after a little will seldom be overlooked. A somewhat different case is where the tympanic membrane is bound to the inner wall in one or more places by adhesions. The free part of the membrane may then form one or more pus pockets, each of which should be incised. When pus is suspected in the middle ear, free incision of the drum is imperative, if we are to give efficient service.

This little operation is simple, easily and quickly performed, and for relief of the pain nearly always magical. It can be done leisurely—therefore, well done—without any pain by using ethyl chloride anesthesia. No assistant is needed. Spread a piece of gauze, or napkin over an ordinary chloroform wire mask. Have the patient in a convenient position. Apply the mask and spray the ethyl chloride on it. In a minute or two the patient is unconscious. Do the work, and two or three minutes later he is wide awake. The opening is safest made in the posterior half of the drum and may reach from near the top to the bottom. If a sickle shaped blade is used, when the bottom is reached, if the point of the knife is turned back and up in withdrawing, a V shaped incision is made. This seems to prevent, or rather to retard too rapid healing of the wound and makes for better drainage; and free drainage in nearly all cases leads more or less rapidly to resolution. As an aid to this, frequent irrigation with normal salt solution or a diluted Dobell's solution is well worth using. Follow by filling the canal with a twenty per cent. organic silver solution. This will often be helpful. A copious discharge will sometimes rapidly diminish by using one in 2,000 mercury bichloride solution in place of the silver. If after a couple of weeks progress is not marked, an autogenous vaccine is valuable. When, however, all are of no value, the tympanic cavity should be drained through the mastoid. The latter is always imperative in the cases that indicate by the clinical course, symptoms, or both, mastoid, meningeal, inner ear, cerebral, or cerebellar involvement. Any one or more of these is of the gravest importance. In most cases they are not easy of recognition. They must be diligently sought and combated decisively, or often the patient will perish. Owing to the anatomical structure of the tympanic cavity, pus in the latter easily flows into the mastoid, and perhaps in all cases of middle ear suppuration the mastoid is infected. It is, however, only in the event of nonresolution that operation is indicated. The patent mastoid infection with pain, tenderness, edema, especially over the tip, all can recognize. We should sadly err, however, if we waited for these, for they all may be absent, and at operation the mastoid may be found filled with pus. In these cases judgment is formed on a recent or continued middle ear suppuration combined with the essential fact that the patient is not well, and is not getting well. A leucocytosis is confirmatory. Epidural abscesses seldom give symptoms and are most often diagnosed at operation. When there are symptoms, they are, tenderness over the site of the abscess and localized headache. In otitic suppuration the pulse much more often than

*Read at the February meeting of the Schenectady County Medical Society.

the temperature calls attention to the absorption of toxic material. It is usually accelerated while the temperature may be normal, sometimes subnormal. Given a case where there had been earache nearly always with, but sometimes without discharge, increased pulse, a moderate leucocytosis, and the patient ill, the mastoid should be opened and tympanum drained. The rapid recovery such patients make is indeed very gratifying.

CASE I. Such a condition obtained in a child of four and a half years. A month prior to being first seen she had a severe pain in her left ear. It lasted all one night and part of the following day. From this time she was off edge—did not eat nor play with zest, and lost weight, although she walked a mile and a half to my office. Examination of the eyes, ears, mastoids, and adjacent parts showed nothing abnormal. There was no tenderness anywhere, but there was a leucocytosis of 11,000. The child neither looked well nor acted well, so on her appearance, the story of the earache without discharge, and the increased white cells, a diagnosis of suppurative mastoiditis was made. This was confirmed at operation, but in addition there was a necrosed area the size of a dime on the skull over the posterior fossa with an epidural abscess. The child was well in two weeks.

CASE II. A somewhat different phase of this disease occurred in a young engineer. He had a double otitis with violent onset. Both drums were promptly and freely opened. The discharge was copious. The patient was very ill for a week, when the drainage gradually decreased with all around improvement. Six days later, the ears were dry, and in another five he returned to work, although not quite himself. The feeling of want of snap deepened, he was not gaining in strength, and his appetite decreased. His only complaint was that there was something the matter for he "did not feel right." His temperature and pulse were normal; moreover, there was nothing about either ear or the adjacent tissues that would suggest a lesion. So on the appearance of the man, his failure to come back, and the leucocytosis, the left mastoid was opened and found filled with pus. In two weeks he returned to work, and has been well since.

The most dangerous, most fatal, and most difficult successfully to combat, are the vestibular, meningeal, cerebral, and cerebellar complications of otitic suppuration. The first can be localized with reasonable certainty, the others can be diagnosed—sometimes. To determine accurately the site of an abscess is not an easy matter, at times impossible, unless symptoms arise that point to the impairment or suppression of a known cerebral or cerebellar function or functions. In any of the foregoing there is usually much headache, often violent, nausea, vomiting, and dizziness. The most distressing attacks of the latter are present when the inner ear is invaded. The suppuration in the middle ear sometimes produces a serous labyrinthitis that may subside, leaving the organ undamaged. On the other hand, when pus enters the inner ear, the case becomes desperate. Nystagmus is a constant symptom, which at first is usually toward the affected side. It diminishes with the subsidence of the inflammation in the serous forms: in the other it ends abruptly and with it the hearing. It is always an indication of a grave condition. The symptoms in intracranial abscess run from the mildest to the most violent. If the abscess can be localized and drained, the prognosis is not hopeless as the following case demonstrates:

CASE III. A school girl of fifteen years, never over strong, suffering for years from headaches, had a severe pain in the left ear. After a night and part of the following day, the ear began to discharge, the pain subsided, and she was again comfortable. This frail girl's mental and physical vigor gradually decreased with a continuance of a scanty ear discharge. Her mother gave little care to the latter and casually asked the doctor for a tonic for her daughter. The doctor suggested that the cause of the girl's ill health probably lay in the discharging ear. This was six weeks after the onset. The suggestion was received with surprise, but acted on. Examination revealed no mastoid tenderness, but much creamy pus in the external canal and a small perforation in the lower posterior quadrant of the membrana tympani. Two days later, there was much less discharge, but some swelling and tenderness over the root of the zygoma. A week elapsed; the canal was dry, the perforation closed, and the tenderness and swelling over the zygoma were gone. The ear was apparently normal and so continued. She returned to school, and during the afternoon of the second day in school, while in a dry goods store, she had an attack lasting about five minutes, in which she was alertly conscious of all about her, but could not recall a single object. Two days later, in the schoolroom, she had a similar but more severe prolonged amnesia. She got home at six o'clock and went to bed. The next day she was much prostrated, temperature 102° F., pulse 130; she vomited many times and had severe left temporal pain. Ear and eye examination negative. The symptoms in a few days subsided somewhat and a consulting neurologist saw nothing, at this time, of consequence. The improvement was marked for the next four days; good appetite, freedom from pain and discomfort, and fair bodily vigor. On one of these days, for half an hour, her right arm, leg, and half of her tongue were asleep. Fourteen days after the initial amnesia, in the morning, a headache of steadily increasing intensity developed and the vomiting returned. These continued, with remission, but never wholly ceased for six days. The temperature was 100° to 101° F., pulse 95 to 105. She was now very ill indeed. During these anxious days, her mother noticed that the girl, when she awoke, was completely bewildered and much annoyed, for she could not name the thing or things she wished. The mother presented one thing after another until the desired one was reached, and even then the patient could not recall its name. Twenty-three days from the onset, Doctor Gordinier saw her. She had an intense pain, a little above and somewhat in front of the left ear. When the pain increased, it radiated to the opposite side and she would vomit. The internal and external ocular muscles, optic nerves, retinas, and bloodvessels were negative. All the superficial and deep reflexes were normal, except the patellar, which were absent, and the tendo Achillis was much diminished. Kernig positive each side; MacEwen's sign absent, no vertigo tremor nor nystagmus. Hearing the same as prior to her illness. The jugulars emptied regularly. She read with ease, intelligently, had no motor aphasia, but did have a slight verbal one. She recalled without effort a dozen familiar things, but could not recognize a knife or shoe horn; yet after studying them and hearing their names, she nodded assent. The pulse was 60 and regular, the temperature subnormal mornings and 99.6° evenings. Blood and spinal fluid normal. Von Pirquet negative. The next day the headache was less and the vomiting more, with photophobia and diplopia; but the optic papillæ were not hyperemic. Hearing hyperacute. From the symptoms Doctor Gordinier made a diagnosis of subcortical abscess of the left temperosphenoidal lobe.

On January 31st, Doctor McMullen trephined the skull an inch and a quarter above Reed's base line and an equal distance posterior to the external meatus. The dura bulged somewhat, but did not pulsate. It was opened. But it was only after the cortex was incised that the abscess discovered itself by yielding about four drams of thick yellow pus. Three days after the operation, a double optic neuroretinitis gradually came on. The discs were elevated 1.5 mm. This continued for more than two months, and for a day or two she had a slight ptosis of the left lid and a decided diplopia. Mornings, on awaking, she had a frontal ache that gradually subsided. The amnesia was much greater than before operation and continued even after she was up and about, in all about six or seven weeks. She miscalled figures, and pictures in the fashion books often had no meaning for her at all. Three months after the operation, all the symptoms were gone. The hearing was perfect and with her high hypermetropic astigmatism

corrected she had vision of 20/10 in each eye. There was no contraction of the visual fields for form or color, and although the neuroretinitis was severe and of long duration, it has left no discoverable lesion of the retina. During the Christmas holidays the patient had a sudden convulsion with loss of consciousness, two weeks ago she had another, and yet one more Sunday morning.

Case IV. A less happy ending occurred in the case of a man of forty years. On a Friday afternoon he felt grippe coming on, and remained in bed the greater part of the following day. Sunday evening he had a sudden violent pain in his left ear. He called his doctor. Monday, the ear began to discharge and the pain subsided. He now suffered a severe headache with nausea, vomiting, and marked dizziness. When not in bed he had to hold on to the furniture to keep from falling. This continued all the week, by the end of which he sat up. The following week, he was little improved, except that the headache and nausea had gone. He continued dizzy, but had a fine appetite, and said he was all right but for his head; this felt queer. After dinner, Thursday, he walked outdoors for three quarters of an hour, returning at 3.30 p. m.; he ate a good supper and went to bed at 6.30. He now complained of an intense headache. At 7.30 his wife found him unconscious and he so remained until death, twenty-three hours later and exactly two weeks from the onset of his illness. The writer saw the patient six hours before death. He was comatose, but retained the pupillary reflexes. Examination of the left ear discovered a small opening near the centre of the drum through which pus was coming. There was much pus also in the canal. The right ear drum was somewhat inflamed, especially at the top. It was incised and a considerable quantity of seropus flowed from the middle ear. There was no edema over the mastoids or cranium. The retina, papillæ, and vessels were normal. A diagnosis of intracranial abscess was made, but its location was indeterminable. Eight hours later, at autopsy, an abscess, one inch in length by a half inch in width, was discovered in the right lobe of the cerebellum. The violence of the symptoms in the left probably masked those of the right ear. No notice, therefore, was taken of the inflammatory process in the right ear. This was very likely infected from the onset, for he complained to his wife, the second or third day, that he was deaf in this ear. The course of the infection was probably through the labyrinth along the acoustic nerve to the posterior fossa. The pathological process in the cerebellum gave rise to the headache, nausea, and vomiting, and was looked upon by the patient and family with little concern. It was the same with the girl (Case III).

This is, in a general way, an index of the appreciation of values the public gives to suppurative otitis media. It is only when disaster results that this very common and very dangerous disease assumes its true perspective. These cases suggest at once some of the dangers, perhaps the difficulties of the management of suppurative otitis media. Luckily, out of the great number of these infections, nearly all go on smoothly to resolution. When, however, complications do follow, they are often among the most formidable. Just how and when the disease is extending in any case is not possible to visualize. The onset of the double choked discs, in the case of the girl after what was even more than a decompression, is remarkable, for this is the procedure after the discs choke for their relief. The long continued inflammation of the optic nerves with complete resolution, is also of interest, for such conditions are usually more or less fatal to vision. Then, too, the epileptic seizures eleven months after operation, are not without interest. From a study of these and similar cases but one deduction can be drawn: that all cases of middle ear infection demand the most careful watching.

11 Lafayette Street.

THE WAKE OF THE WASSERMANN TEST.

By James Cabell Minor, M. D.,
Hot Springs, Ark.

At steady and increasing speed the Wassermann test plies the waves of the sea, lues venerea. Is this craft a devil's plaything for inquisitive doctors, or is it a boon to humanity? Think of the wretches it leaves in its wake! Should patients with past history of lues venerea be apprised of the findings in all cases of the laboratory when the Wassermann reaction is obtained? I say no.

It is no more necessary to reveal to our patients our laboratory findings than it is to attempt to explain to them the physiological action of the drugs or remedies we employ to treat the malady. We *know* as little of the accuracy of the one as we do of the other. Yet, we all do it.

Laboratory tests are invaluable to the doctor in directing treatment, and soothing and quieting the psychic temper of the patient, but it is for the doctor and the doctor only to reveal to the patient the findings of the laboratory, and it is for him to rate the values of the tests and make the revelation in the most delicate way at the proper time. I do not believe we should announce to patients laboratory findings and by no means permit the uncanny, unintelligible, confounding symbols to be handed them to ponder and brood over, for they do not and cannot fairly interpret such reports.

In the past few years it has pained me to witness in apparently healthful and useful and happy men and women the baleful effects of the laboratory reports bearing the uncanny four plus wireless from the Wassermann. I could cite a hundred patients on whom the Wassermann "wireless" has had disastrous effects according to the personal feelings and belief of the patient.

I will mention here only three distressing cases wherein ignorance was bliss.

A prospective groom comes on the stage in the doctor's office. He weighs 169 pounds; is built like an Apollo, he is athletic, a golfist, rider, social and business leader, of moderate habits, commands an enviable position in a big concern, he is happy and care free. Physical examination reveals no blemish either functional or structural (except that there is inequality in one or more of the reflexes). He carries life insurance in one of the old line companies. His doctor at home has told him if he had a daughter and they wanted to marry they could get his free consent.

Said he to me, "Doctor, I am to be married next month, and I recall that about twenty years ago I had a little sore, and the old doctor told me to be on the safe side and take treatment. I did so. I have never had the slightest trouble or blemish since, but in my State they may require a Wassermann before issuing the license. Will you direct one for me?"

"Sir," I replied, "I have examined you carefully for all signs or symptoms of latent syphilis; I find you in excellent physical condition. Your resisting power to the ravages of any disease is perfect. Why should you be in this splendid trim if there remain in you harmful elements of the disease? Why should it militate against your procreating average

children any more than your having had years ago typhoid fever or diphtheria? If you were now in a low state of vitality from past or present syphilitic infection, or from typhoid fever or tuberculosis or alcoholism or any other systemic affection, I would seriously object to your marriage. You can do as you please. I do not approve of your having a Wassermann test." But twenty-four hours afterward, the Wassermann test read four plus. A different human aspect was presented. A few days later, he was pale and dejected, disgusted. His appetite was gone, his nights were sleepless; I was forced to tell him that he should take up the specific treatment.

He lost ten pounds in weight and became a pitiable object physically. He left; "got a telegram, got to go home, things not going right." And indeed they have not gone right with that fine fellow. In despair he is seeking the 606 and spinal puncture artists. No wedding bells! That "glass of fashion," that "mould of form," that "observed of all observers" has become a recluse in a cell of misery.

And here is what happened to a bride-for-the-second-time, who in all candor before the wedding told husband number two what husband number one had done for her fifteen years ago. The two came to the office happy and in high spirits; both were enjoying golf and horseback riding as a daily sport and were on the ballroom floor in the evenings. She was a picture of health. "Doctor," said she, "we are here to enjoy the climate and the baths, but while here at your famous resort à la Aix-la-Chapelle, I should like to make sure that I am perfectly free from that horrid disease of fifteen years ago, so I wish you would direct a Wassermann test. I have always doubted my having it at all." I made a careful examination of the woman. "My dear madam, why chase up something ugly as long as your beauty and splendid physical condition do not at present reveal disease either to you or to me? I have examined you and find no reason for disturbing Nature's admirable work. Why not just go on as you are in your present healthful and happy condition? I object to your having the blood test made." They went, however, to a reliable laboratory, and in eighteen hours received the fateful four plus message. They gave up golf, riding, and dancing. They have quarreled since and separated. She returned to her estates in England. He lives at a club in New York.

An elderly gentleman beaming with the satisfaction begotten of a successful business career, and feeling with just pride that he and his wife and charming grown daughters could now enjoy the fruits of his labors, was prominent on the golf links, the ballroom floor, and equestrian fields. His "foot slipped some thirty years ago," so he told me he wanted to have the satisfaction in his declining years of knowing that he was leaving his wife and daughters above reproach. I declined his invitation to direct a Wassermann, but he found a good laboratory and the real four plus stuff in a few days. When he came to me again he was pitiably dejected, became morose, apathetic, ambitionless, and soon left for his home a sadder but wiser (?) man. There are laboratories in Hot Springs, Ark., reliable perhaps as to findings, but I know of only two chemists who refuse to give the patient the report or discuss it without permission of the doctor.

This article is intended and offered simply as a suggestion to doctors and chemists to be more careful and delicate, hereafter, in giving to the patient the gruesome tidings from the Wassermann.

306-307 Dugan-Stuart Building.

Contemporary Comment

A Charity Endowed in Lord Kitchener's Name.—An appeal for a National memorial fund to commemorate the late Lord Kitchener was made by the Lord Mayor of London on July 14th and met with an immediate response, a sum of £18,000 ($90,000) being contributed by noon the following day, says the *Canadian Medical Association Journal* for September. The income from the money thus obtained is to be devoted in perpetuity to providing for officers and men of the Royal navy and army who have been disabled and whose pecuniary circumstances preclude them from obtaining such attention and comforts as they need. A portion of the fund will be applied immediately to the equipment of a home for disabled officers for whose assistance nothing of a permanent nature has yet been considered. It has been the desire that the memorial chosen should be permanent and should perpetuate Lord Kitchener's name for all time and that it should be devoted to some object in which Lord Kitchener was known to be particularly interested. No more fitting object could be found than the welfare of the King's forces.

Enormous Loss from Typhoid Fever and Malaria.—The *Pacific Medical Journal* for September, 1916, makes several citations from a recent address by Senator Joseph E. Ransdall, of Louisiana, on Rural Health, America's First Duty: "The estimated economic loss which our nation suffers each year from typhoid fever and malaria alone aggregates $928,234,880, leaving out of entire account the sorrow, the unhappiness, the misery, and the inefficiency which follow in their train. The greatest asset which our country can have is the healthy American citizen, and valuable as it may be to increase the health of live stock and vegetation, it is of far greater importance that we throw every possible safeguard about the health of the man who is responsible for that live stock and vegetation. Over 900 million dollars lost every year! A sum which is sufficient to put our country into a state of preparedness equal to that of any nation in the world, enough money to give us the largest navy afloat and the most efficient army which the world has ever seen, is annually offered up as a sacrifice to two diseases which are entirely preventable. Enough money to pay the annual expenses of every college student in the United States is thrown away every year." Senator Ransdell estimates the total loss from typhoid fever at $271,932,880, and the loss from malaria at $694,904,750 per annum; the total per capita loss from these two diseases being $9.46. By comparative estimates it was shown that the United States Government appropriated $5,016,175 for the investigation and prevention of the diseases of animal and plant life and only $1,917,566 for the investigation and prevention of the diseases of man.

FOCAL INFECTIONS.

For many years it was thought that we were well acquainted with bacteria and their vagaries, but recently we have discovered that there remains much to be learned. Of the various activities of bacteria the most interesting at present is that of the so called focal infection. By this is meant a small, more or less quiescent point of disease, which although it causes no local disturbance, gives rise to symptoms elsewhere in the body.

Probably the most important of these manifestations is the involvement of the various joints of the body. If we pick up our textbooks to read about arthritis, the chances are that we shall be much discouraged, not only by the unfavorable prognosis, but also by our inability to determine the cause. Since the work of Rosenow and others, however, we are fast realizing that a small collection of bacteria may be responsible for the joint condition, and we also are discovering the fact that the only way to accomplish much good is to attack the primary focus.

At present the capable physician is no longer content to give antipyretics, in expectation of a miraculous cure. If a patient now gives a history of chronic and painful joints, the first thought of his physician should be focal infection. To determine the presence or absence of such a condition is not always an easy task, and outside aid, particularly the Röntgen ray, may have to be called upon. There may be a chronic gonorrhea, the tonsils may be diseased or, what is very common, there may be infection at the roots of the teeth. This last is a frequent condition and may be present without local indications. It is also interesting to note that many inflammatory lesions of the eye are directly referable to dental infections. This has long been recognized by the laity, but the idea was considered to be mere superstition by the medical high priests.

After removal of the focal infection the patient's rapid recovery, in many instances, is little short of marvellous. In most cases no farther treatment seems to be necessary, the joints cease to be painful, and the convalescent goes on his way rejoicing.

That bacteria in the foci cause the distant lesions has been proved so many times that there can now be no doubt as to the causal relation. The isolated organisms, when injected into experimental animals, show a special affinity for tissues similar to those involved in the original instance. A joint will be attacked, an eye become involved, even the appendix will succumb, according to the affinity shown in the first case.

The more thoroughly the matter is investigated, the clearer it becomes that focal infection seems to explain satisfactorily certain of the hitherto unsolved problems of medicine.

HEALTH IN CITY AND COUNTRY.

There can be no question that, at the present time, the sanitary conditions, as we usually understand them to be, of the city are superior to those of the country. Certain infectious diseases, such as malaria, typhoid, whooping cough, and influenza, are more prevalent and the toll of life from these agencies is proportionately greater in the smaller than in the larger communities. This fact is obviously due chiefly to ignorance of the laws of sanitation, or rather to lack of intelligent supervision of water and milk supplies and of drainage. These conditions which war against health are being improved, however, and the disparity in healthfulness from these causes is not likely to continue.

The city has little reason to congratulate itself, even at the present time, upon its superior sanitariness. If it does so it follows the ostrich fashion of tucking its head into the sand of this one item of superiority—its freedom from noxious bacteria.

Sanitation is a much more inclusive term than we commonly conceive it to be, and it should mean much more than the mere prevention of sickness and premature death from typhoid, diphtheria, or malaria; these aside, the suburbanite fares better than his urban cousin. The most evident proof is the fact that the work of the world, transacted largely within city limits, is directed in something like eighty per cent. of cases by men who were born and spent their early days in the country. The heads of great businesses, of great educational and other institutions, come, in large majority, from the rural regions. To say that this depends on the superior mental training received in the country school, or, what is nearer the truth, from the daily experiences of country life, is to admit that the elaborate and apparently superior machinery of city schools has less to do with real education than we commonly suppose. It is alleged that the detail work in business offices and elsewhere in our cities is done with less care than it was two decades ago. Though the opportunity for mental training is not to be despised, it amounts to little if there is a physical basis which neither allows of the full effect of the training at the time it is received, nor its use afterward in the work of life. Capacity for work depends upon two factors, intensity and endurance; the city child shows plenty of intensity, but endurance is lacking.

Another piece of evidence which condemns the salubrity of the city, is that its own population soon dies out and must constantly be renewed from the country. Whether this is due to the more strenuous life led by the city dweller, to the greater expense of supporting a family, or to other more directly physical causes, the conditions producing the deterioration and termination of life are as much insanitary as those which allow typhoid or tuberculosis germs to flourish and destroy mankind. Sanitation must in future mean more in proportion to the degree of vitality it allows than in the number of cases of illness or of death it prevents.

The cities contain now most of the population of the land, and have drained and are still draining the rural districts of their most enterprising, and therefore most robust people. The country may be insanitary on the surface, but the city is insanitary from causes which lie deep but not too deep to be uncovered. It is bad for a few people in a community to die of certain infectious diseases, but it is worse for the many to live lives on a low level of vigor. A study of the causes of the inferior vitality of the human product of the city, that these unhealthful conditions may be, if possible, corrected, is one of the present needs of our national life.

WEIL'S DISEASE.

Infectious jaundice was first described as a disease entity by Weil in Germany, in 1886, but it was probably well known long before that, for in our Civil War over two per cent. of our soldiers suffered from an infectious jaundice. However long the disease may have been known, its cause has remained undiscovered, but the recent investigations of Uhlenhuth and Fromme (*Berliner klinische Wochenschrift,* March 16, 1916) now seem to have led to the discovery of the specific infectious agent.

With the outbreak of the European war there was a considerable prevalence of this infectious jaundice, and with the abundance of material Uhlenhuth and Fromme set out to find the cause of the disease. They were able to reproduce the disease in guinea-pigs by inoculation of fresh blood from human cases. Microscopic study of the tissues of the infected pigs revealed the presence of great numbers of spirochetes in the liver. It was also possible to demonstrate this organism in practically all other tissues of the pig, including the blood, although in relatively small numbers. A few instances were also encountered in which apparently the same organism could be demonstrated in the liver in fatal human cases.

The organism could not be artificially cultivated, but its specific causal relation to Weil's disease was proved by the following facts, in addition to those just mentioned. First, the disease could be transferred from pig to pig, showing the multiplication of the organisms; active immunity was developed against it in man and animals; the removal of the organism by filtration completely deprived the suspensions of infective pig's tissues of their infectiousness, lastly, some degree of passive immunity toward infection could be secured by the use of immune serum from cases which had terminated favorably.

These new studies have not only apparently led to the discovery of the causal organism, but they have added to our knowledge of Weil's disease in two other directions. In the first place they have provided a means for testing the effectiveness of therapeutic agents, showing already that such drugs as neosalvarsan, colloidal silver, collargol, colloidal antimony, mercury atoxyl, silver atoxyl, atoxyl, and optochin were without curative action. Disappointing as this is, however, the way is now open for the elaboration of an effective remedy, and immune rabbit serum is now being tried with some success.

The second contribution these studies have made is that the infectious spirochete may gain access to the body through abrasions of the skin and through certain intact mucous surfaces, such as the conjunctiva. Finally the parasite has proved to be

easily destroyed by drying, by heat, and by dilute antiseptic and bactericidal agents. In this day when antivivisectionists are waging active war upon the advance of medical science, we cannot refrain from calling attention to the fact that these initial steps in the conquering of one more disease have been made possible solely through animal experimentation.

THE ACTION OF DRUGS ON THE CIRCULATION IN THE BRAIN.

Recent advances in the study of the intricate functions of the different organs, particularly the ductless glands, disclose a new series of phenomena with regard to the action of drugs, hitherto unsuspected. Our previous conceptions concerning the physiological effects of the better known drugs are crude in the light of later studies. Generally speaking, we have been considering the massive action of drugs, assuming that a certain drug acts on the motor, the sensory, or the sympathetic nervous system, as a whole. The newer studies of the autonomous division of the sympathetic brought to light the fact that a given drug which acts, for instance, on the circulation, may affect one set of organs and not another, depending on whether the organ is supplied with nerves from the autonomous system. Thus, we can understand how adrenaline, which causes a characteristic constriction of the vessels of the liver, produces dilatation of the pulmonary vessels. Difference in action is also observed in the organs of different animals, caused no doubt by the difference in the nerve supply. Thus histamine and barium chloride constrict the peripheral vessels, the veins, and the pulmonary vessels of a rabbit, but have no such action on a frog's liver. Fever and inflammation seem to modify the action of drugs, as evidenced by the fact that adrenaline has no constricting effect when the temperature is elevated, acting then as a vasodilator. Antipyrin has no action on the cerebral vessels of a normal animal, but acts also as a vasodilator in the presence of fever.

The action of drugs on the circulation in the brain has been studied with varying results, some investigators maintaining that cerebral vessels do not possess vasomotor nerves. This view, however, has been shown to be erroneous by a number of physiologists. The sum total of the investigations shows that chloroform, amyl nitrite, strophanthin, caffeine, phenocol, p-aminophenol, pyramidon, cocaine, and chloral hydrate produce dilatation of the cerebral vessels, while adrenaline and salicylic acid act as vasoconstrictors. Alcohol was found by some to have a vasodilator effect, and by others no effect at all. V. I. Berezin (*Roussky Vratch*, May 28, 1916) instituted a number of experiments on the isolated brains of carp and rabbits, the latter being used as controls. He found the following substances to act as vasodilators: Alcohols, hypnotics (amylen hydrate, sulphonal, trional, tetronal, urethane, hedonal, veronal, and chloral hydrate); narcotics (ether, chloroform, and acetone); caffeine, camphor, atropine, antipyrin, quinine, and salicylic acid. On the other hand, nicotine, adrenaline, histamine, morphine, strophanthin, and barium chloride act as vasoconstrictors. His observations showed that not only do the cerebral vessels possess vasomotor nerves, but they differ from the peripheral vessels in greater latitude of action, resembling in this respect the vessels of the internal organs, the liver, the lungs, and the heart. Incidentally, the fact that hypnotics and narcotics dilate the cerebral vessels deserves notice as discrediting the view that their action depends on the production of cerebral anemia.

GASOLINE FOR CLEANING WOUNDS.

M. H. Embree, R. A. M. C., communicates to the *British Medical Journal* for September 2, 1916, some of his experiences with gasoline (petrol) in the cleansing of wounds. It has been in use for twenty years, he says, in the hospitals of Toronto, Ont., to cleanse contused, lacerated wounds with dirt ground into them. As wounds received at the front are contused, lacerated wounds, and come in a very dirty condition, it seemed worth while to try gasoline in cleaning them; the method used in his field ambulance for the first cleansing of wounds is as follows:

The skin, and then the surface of the wound, is cleaned by vigorous rubbing with a swab of absorbent cotton soaked in gasoline. Swabs of cotton are wound round an artery forceps or probe and soaked in gasoline, and with them the wound is cleaned from the surface inward as far as the forceps can be pushed. The forceps is rotated and pushed in all directions, a number of swabs being used, and the process is continued until a couple of swabs come out perfectly clean. If there is much dried blood or gross dirt on the surface of the skin or wound, it is best removed with warm water and soap, and a brush if necessary, before the gasoline is used. The gasoline does not cause any special smarting, and patients did not complain of it when questioned. If gasoline is left wet on the skin and jaconet or adhesive plaster strips close together are applied over the dressing, preventing evaporation, there will be blistering of the skin, but otherwise this does not occur.

Gasoline used in the manner described certainly seems to clean up the surface, and particularly the depths of wounds better than any other method that has been tried. If we are not mistaken, workmen in industrial plants in the United States have long been thoroughly versed in the effective use of gasoline in first aid treatment of dirty cuts and lacerations.

News Items

A Memorial to Doctor Murphy Planned.—It is reported that a $500,000 memorial to the late Dr. John B. Murphy is to be erected in Chicago. It is believed that this memorial will be in the form of an institution for surgical research.

A New Directory of Philadelphia Hospitals.—A new edition, revised to date, has been issued of the *Handbook of Philadelphia Hospitals and Dispensaries.* Copies may be obtained, at fifteen cents each, from the Social Service Department of the Episcopal Hospital, Lehigh Avenue and Front Street, Philadelphia.

Misericordia Hospital Cornerstone Laid.—On Sunday, September 24th, the cornerstone of the new Misericordia Hospital of the Sisters of Mercy, at Fifty-fourth Street and Cedar Avenue, Philadelphia, was laid with elaborate ceremonies. The estimated cost of the new institution is $1,500,000.

A Medical Department for the Boston Police Court.—It is reported that the Boston City Council has passed an ordinance that will give to the city police court a medical department and a psychological laboratory, of which Dr. Victor V. Anderson will have charge. The mental condition of all offenders will be passed upon by this department before sentence is pronounced.

New Offices Created in the District of Columbia Health Department.—The appropriation bill enacted by Congress on September 1st provides for the appointment of a chief medical and sanitary inspector, who will give his whole time to the direction and control of the medical and sanitary conditions of the public schools, at a salary of $2,500. A chief food inspector will also be appointed, to have general supervision and control of food inspection, at a salary of $1,800.

Oregon State Medical Association.—At the Forty-second annual meeting of this association, held in Portland, September 14th and 15th, Dr. R. C. Yenny, of Portland, was elected president, succeeding Dr. W. Kuykendall, of Eugene. Other officers were elected as follows: Dr. H. J. Clemens, of Salem, first vice-president; Dr. Leo Chilton, of Canyon City, second vice-president; Dr. C. J. McCusker, of Portland, secretary; and Dr. Katherine C. Manion, treasurer.

Diagnostic Aids in Medicine and Surgery.—At a stated meeting of the Northern Medical Association of Philadelphia, Friday evening, September 29th, this subject was discussed as follows: Dr. J. Solis-Cohen, the Laryngoscope; Dr. Samuel Wolfe, the Stethoscope; Dr. William H. MacKinney, the Cystoscope; Dr. Samuel Horton Brown, the Ophthalmoscope; Dr. Sidney L. Feldstein, the X Ray; Dr. John A. Kolmer, the Laboratory; Dr. F. A. Faught, Blood Pressure. A general discussion followed.

Dinner to Doctor Aikman.—On Tuesday evening, September 26th, Mr. A. R. Elliott, president of the A. R. Elliott Publishing Company, gave a dinner at the Hotel Brevoort to Dr. John C. Aikman, who has been associated with the subscription and advertising departments of the New York Medical Journal for the past twenty years, and who has retired to accept a position as secretary, treasurer, and general manager of the National Pathological Laboratory of New York. The guests included the editorial staffs and the department heads of the Elliott publications.

Changes in the Medical Faculty of Tufts College.—Several changes are announced in the faculty of the medical and dental schools of Tufts College, Boston, among them being the following: Dr. Andrew H. Ryan, who has been connected with the faculties of the University of Pittsburgh, Washington University, and the University of Alabama, will take charge of the department of physiology in both schools; Dr. Charles H. Bailey, of Leland Stanford University, has been appointed associate professor of histology; Dr. R. Harman Ashley, of the University of Maine, will take charge of the department of chemistry in the dental and premedical courses; Dr. Arthur L. Chute has been advanced from assistant professor to associate professor of surgery.

American Ambulances for Russia.—Fifteen motor ambulances have been presented by a group of Americans to the field hospital service of Russia and have gone to the front under command of Dr. Philip Newton.

Pharmacy, Old and New.—The Philadelphia College of Pharmacy held an exhibition in their college buildings last week of modern scientific pharmacy contrasted with pharmacy of a century ago. The exhibit included a drug store of 1812, with many interesting historical exhibits; exhibits of modern pharmaceuticals and chemicals; a professional pharmacy fully equipped with scientific laboratories and ready to cooperate with the medical profession in the modern practice of medicine.

Harvard Medical School Establishes Infantile Paralysis Commission.—Dr. Robert W. Lovett, professor of orthopedic surgery at Harvard Medical School, is chairman of a commission established by Harvard University to learn how to combat infantile paralysis successfully. The other members of the commission are Dr. Milton J. Rosenau, professor of hygiene and preventive medicine, Dr. Francis W. Peabody, assistant professor of medicine, and Roger Pierce, secretary.

How Life Begins is the title of a motion picture film exhibited privately by the American School Hygiene Association at the Russell Sage Foundation, Wednesday afternoon, September 27th. This film was produced by Mr. George E. Stone, of Berkeley, California, in collaboration with Dr. J. A. Long, professor of embryology at the University of California. It tells the story of how new plants and animals come into existence, and presents phases of plant and animal activity in the field and under the microscope, which are unique in motion picture production.

Personal.—Dr. I. J. Kligler, who has been in charge of the bacterial collection of the department of public health of the American Museum of Natural History, has resigned to accept a position with the Rockefeller Institute for Medical Research.

Dr. Ross V. Patterson, recently appointed dean of Jefferson Medical College, to succeed Dr. James W. Holland, assumed his new duties at the ninety-second annual session of the board of trustees of the college, on Monday evening, September 25th.

Professor Charles Richet, of the University of Paris, has been awarded the State prize for poetry. His subject was the Glory of Pasteur.

The Second National Exposition of Chemical Industries was held during the week of September 25th at the Grand Central Palace. Nearly two hundred exhibitors, covering all the large chemical industries, participated in the exposition. The fact that the meeting of the American Chemical Society, the American Electrochemical Society, and the Technical Association of the Pulp and Paper Industry were held during the week brought together several thousand chemists. Among the speakers at the opening of the exposition were Dr. Charles H. Herty, president of the American Chemical Society; Dr. Francis A. J. Fitzgerald, president of the Electrochemical Society, and Mr. Thomas J. Keenan, secretary of the Technical Association of the Pulp and Paper Industry.

Motion Pictures Applied to the Teaching of Surgery.—For the first time motion pictures have been applied as an aid to the most difficult operations in surgery. On Monday next, at 1 p. m., Dr. S. William Schapira will lecture at Fordham University on various genito-urinary operations, and will illustrate his lecture with motion pictures of actual operations performed by him. These pictures cover thirteen distinct operations, and were made by a Pathé camera man under Doctor Schapira's direction. In the past surgical lectures have been illustrated by still pictures or drawings and much of the detail has been lost; in these motion pictures every movement is clearly shown. Among the operations shown are nephrectomy, nephrotomy, nephrolithotomy, nephrorrhaphy, nephropexy, pyelotomy, ureterotomy, suprapubic cystotomy, suprapubic prostatectomy, external urethrotomy, orchidectomy, varicocele, hydrocele, amputation of penis, and cystoscopic operations.

Examination for Assistant Physician, State Institutions.—Among the positions for which the New York State Civil Service Commission will hold examinations on November 4th, is that of assistant physician for State prisons and reformatories; salary, $2,500 without maintenance. The examination is open to men only who are licensed medical practitioners in New York State and who, since graduation, have had at least one year's experience on the resident medical staff of a general hospital. There is at present one vacancy at Sing Sing.

Meetings of Medical Societies to Be Held in Philadelphia during the Coming Week.—Monday, October 2d, Wills Hospital Ophthalmic Society, Academy of Surgery, Philadelphia Clinical Association, Blockley Medical Society; Tuesday, October 3d, Aid Association of the Philadelphia County Medical Society (directors), Laryngological Society; Wednesday, October 4th, Physicians' Motor Club (directors), College of Physicians; Thursday, October 5th, Obstetrical Society, Southeast Branch of the County Medical Society; Friday, October 6th, Kensington Branch of the County Medical Society.

Utah State Medical Association.—Dr. S. C. Baldwin, of Salt Lake City, was elected president of this association at the twenty-second annual meeting, held in Salt Lake City on September 12th and 13th, succeeding Dr. E. W. Whitney, and other officers were elected as follows: Dr. J. R. Morrell, of Ogden, first vice-president; Dr. P. M. Kelley, of American Fork, second vice-president; Dr. D. C. Budge, of Logan, third vice-president; Dr. F. A. Flood, of Salt Lake City, treasurer; Dr. H. G. Merrill, of Provo, counsellor for the third district. Dr. W. Brown Ewing, of Salt Lake City, has still two years to serve as secretary.

Jefferson Medical College Alumni Hold Reunion.—The tenth annual reunion of the New England Association of Jefferson Medical College Graduates was held in Hartford, Conn., on Tuesday evening, September 19th. Dr. Eckley R. Storrs, of Hartford, was elected president, Dr. Albert C. Getchell, of Worcester, vice-president, Dr. Wallace P. MacCullum, of Boston, secretary, and Dr. Frank I. Payne, of Westerly, R. I., treasurer. At the banquet which followed the business meeting, Dr. J. W. Felty, of Hartford, acted as toastmaster, and among the speakers was Dr. Edward P. Davis, of Jefferson Medical College.

Social Service School Opens.—The reorganized Pennsylvania School for Social Service was opened on September 25th for the season, with over thirty students enrolled. Mr. Bernard J. Newman, formerly general secretary of the Philadelphia housing commission, is the new director. Among the lecturers will be: Dr. Carol Aronovici, director of the bureau of social research; Dr. Louise Stevens Bryant, chief of the psychological clinic, domestic relations court; Dr. Nathaniel Gildersleeve, professor of bacteriopathology, University of Pennsylvania; Frederick P. Gruenberg, director of the bureau of municipal research, and Dr. Carl Kelsey, professor of sociology, University of Pennsylvania.

The Harvard School for Health Officers.—Sixty courses of study will be given, beginning this autumn, in the School for Health Officers conducted by Harvard University in conjunction with the Massachusetts Institute of Technology. The faculty will be composed of fifty members. The principal object of the school is to prepare young men for public health work, and especially to fit them for the occupancy of administrative and executive positions as health officers or members of boards of health. To this end both institutions will offer lectures, laboratory work, and other forms of instruction, and men from National, State, and local health agencies will speak. The subjects embraced in the course of study have been selected to cover a wide range, including medical, biological, hygienic, and engineering sciences, together with practical health administration. The courses to be given are divided into ten groups dealing with various phases of sanitation problems. The certificate in public health (C. P. H.) will be granted to candidates who have satisfactorily completed the studies in their approved schedule, who have spent not less than one academic year in residence, and who have otherwise complied with all requirements.

Lectures on Mental Health.—The program of public lectures arranged by the Department of Education of the City of New York to be given during the months of October, November, and December, includes six lectures on mental hygiene, as follows: Wednesday, October 11th, Homer Folks, LL. D., Why So Many People Go Insane; October 18th, Mr. George A. Hastings, The Social Cost of Mental Disease; October 25th, Dr. Stewart Paton, Preventable Mental Diseases and How to Prevent Them; November 1st, Dr. Ira S. Wile, Social Hygiene an Aid to Mental Health; November 8th, How the Empire State Cares for 34,000 Insane; Dr. Henry Smith Williams, Importing Insanity. This course of lectures has been arranged in cooperation with the Mental Hygiene Committee of the State Charities Aid Association.

Red Cross Nurses at the Mexican Border.—To reinforce the Army Nurse Corps on the Mexican border the War Department has obtained from the American Red Cross 125 graduate Red Cross enrolled nurses for assignment to camp and base hospitals distributed along the frontier from Nogales, Ariz., to Brownsville, Texas. Fifteen of these 125 are representative of big civil hospitals in which American Red Cross base hospital units have been organized by Colonel Jefferson R. Kean, Medical Corps, United States Army, Director General of Military Relief of the Red Cross. The nurses were selected by Miss Jane A. Delano, chairman of the National Committee on Red Cross Nursing Service, whose department has over 7,000 enrolled graduate nurses. While Colonel Kean has organized twenty-five base hospitals, eight only of these will be represented in this detail of 125 nurses.

Pennsylvania State Medical Society.—The following officers were elected at the sixty-sixth annual meeting of the society, held in Scranton, September 19th, 20th, and 21st, under the presidency of Dr. Charles A. E. Codman, of Philadelphia: President, Dr. Samuel G. Dixon, commissioner of health of Pennsylvania; first vice-president, Dr. J. B. Corser, of Scranton; second vice-president, Dr. W. A. Albright, of Munsey; third vice-president, Dr. George H. Boyer, of Allentown; fourth vice-president, Dr. J. O. Wagner, of Beaver Springs; secretary, Dr. C. L. Stevens, of Athens; assistant secretary, Dr. C. P. Franklin, of Philadelphia; treasurer, Dr. G. W. Wagner, Johnstown. The board of trustees of the society was reorganized by the election of Dr. Theodore B. Appel, of Lancaster, as chairman, and Dr. F. L. Van Sickle, of Olyphant, clerk. Next year's meeting will be held in Pittsburgh.

The American Chemical Society held its fifty-third meeting in New York from Monday, September 25th, to Saturday, September 30th, at the official headquarters, the Chemists' Club, 52 East Forty-first Street. The general meetings were held at Columbia University, the section meetings at the Chemists' Club, Grand Central Palace, and the New York College of Pharmacy. Several thousand chemists were registered, the membership having increased over 1,000 last year and being now above 8,000. A reception was held at the Hotel Astor on Tuesday evening, September 26th, a smoker on Wednesday, and a banquet at the Waldorf-Astoria on Friday evening. The ladies were entertained with luncheons, automobile tours, a theatre party, a view of New York from a yacht, and a shopping tour of the city. The meeting was presided over by Dr. Charles H. Herty, of the University of North Carolina. Among the general addresses were the following: General William Crozier, chief of ordnance, War Department, on Chemistry and the National Welfare; John E. Gardin, vice-president National City Bank, on Chemistry and Banking; Gifford Pinchot, president, National Conservation Association, on Chemistry and Conservation; and Charles H. Herty, president, American Chemical Society, on Expanding Relations of Chemistry in America. The Industrial Chemical Conference was held on Friday and a number of papers in various sections were read which touched on matters of interest in medicine. The Technical Association of the Pulp and Paper Industry and the American Electrochemical Society had concurrent meetings and took part in some of the divisional meetings.

THE THERAPEUTICS OF A PHARMACOLOGIST.

By A. D. Bush, M. D.,
Professor of Pharmacology and Therapeutics, University of Southern California.

Thirty-eighth Communication.

CATARRHAL INFLAMMATIONS OF THE NOSE, THROAT, AND LARYNX.

Treatment of these affections resolves itself into local and systemic measures, depending on the time when the patient comes under observation. Early in these diseases it sometimes seems possible to so aggravate nature with drugs that the illness is abated incidentally to a general reaction of the system to the more potent toxin. Whether it be rhinitis, pharyngitis, or laryngitis, the early administration of small doses of belladonna seems to cut short what otherwise would apparently have been a debilitating attack. It is well to say "apparently," since in any abortive case it is impossible to know positively whether the drug actually induced the cure or whether nature itself was adequate, despite the drug; this is a fair question, since not infrequently the drug fails to act in orthodox fashion. This very lack of definite demonstrability admits of multitudinous therapeutic claims being foisted upon the ever receptive profession and the always gullible laity. The only wise course is to administer those drugs only whose pharmacological provings show fairly clear indications for present utility, and even then many of these indications are simply symptomatic.

In each of these inflammations of the upper respiratory tract, there is usually marked congestion of the mucous membrane followed by extensive mucous secretion, more in the nose than elsewhere. No drug seems to have so pronounced a repressive effect on this mucous leakage as belladonna; it exerts its influence on the nerve terminations in such a way as to inhibit impulses to the glandular secretory apparatus; without these impulses the glands fail to pour out the excess of secretion characteristic of catarrhal inflammations, and it is a fair assumption that the microbes responsible for these diseases find that a subnormally moist mucous membrane is an unfavorable habitat.

There is no particular evidence that belladonna causes a diminution of the blood supply to these mucosæ, unless indeed the resulting congestion of the cutaneous capillaries relieves to some extent the deeper structures. This rather improbable suggestion is perhaps the sole reason for administering small doses of aconite with the belladonna, as the tacit assumption in the small dose is the obtaining of a peripheral effect without causing depression of the heart at the same time. The older plan of using aconite as a regular treatment for acute catarrhal attacks of the respiratory tract, and still employed in sthenic cases, implied actual cardiac depression as a means of relieving the sharp, general venous congestion; but this plan is no longer regarded with favor.

Another treatment widely recommended is the administration at bedtime of a moderately generous Dover's powder. The clinical consensus as to the merits of Dover's powder in these affections is too general not to merit investigation, yet it is not easy to find adequate pharmacological explanation and justification. A diaphoretic effect is presumed; yet though opium diminishes all the secretions of the body except those of the sweat glands, there is no satisfactory evidence that the drug therefore increases or in any way stimulates the activity of these glands; the only effect ipecacuanha has on perspiration is the reflex incidental to nausea in general. Opium usually produces a relaxation of the peripheral arterioles of the face and neck, and it may possibly favor freer skin activity over the rest of the body. Possibly, too, the lowered consciousness of the patient, another effect of the opium, makes him indifferent to the extra bed covering, which may be the real factor in promoting diaphoresis.

So many of the catarrhs of the upper respiratory tract are due to overeating and alimentary plethora that a good purge, sweeping the entire canal, is almost invariably beneficial as the first step in the treatment. For this purpose, senna, for children, and the compound vegetable pill for adults, serve much better than the more commonly administered calomel.

Other drugs recommended by some writers and practitioners are quinine, camphor, the salicylates, and the coal tars; but unless these drugs are *specifically* indicated by some easily recognized systemic dyscrasia, they should not be used at all in catarrhs of the nose and throat.

Cleansing of the nasal mucosa with mild alkaline solutions is highly desirable; and this cleansing may well be followed by a spray of some bland oil containing 0.1 per cent. of menthol, though in some very sensitive types menthol only adds to the irritation and congestion. This engorgement of the Schneiderian membrane may best be reduced temporarily, at least, by swabbing or spraying with epinephrine solutions. Epinephrine is certainly much safer and better to use than is cocaine, so frequently recommended, as cocaine not infrequently affects the patient unfavorably in a systemic reaction.

Steam inhalations, medicated with the compound tincture of benzoin or with the oil of eucalyptus, is a satisfactory method of local treatment in laryngitis.

Exclusion of the Pylorus.—O. Giovanni (*Gazzetta degli ospedali e delle cliniche*, August 3, 1916) describes a method evolved by him from experiments on animals to exclude the pylorus. He inverts the serous coat of the pyloric tract into the lumen of the bowel, bringing it in contact with the mucosa, which has been denuded in order to form adhesions.

Treatment of Paroxysmal Tachycardia.—M. Villacorta (*Cronica Medica*, July, 1916) recommends compression of the pneumogastric nerve or its electrical stimulation, tickling of the pharynx to provoke vomiting, the swallowing of large mouthfuls of bread to distend the esophagus and the dorsal posture with deep inspirations and retention of the air in the lungs for several moments. Vomiting may be produced by ipecac or other emetics, while pituitary extract has been advocated by Boez and Vaquez. An icebag to the precordium may help and antispasmodics may be required, such as the bromides, valerian, belladonna, and morphine. To prevent the return of the attacks the nervous system shold be soothed by tepid baths, moderate exercise and repose both physical and mental.

Radium Therapy.—Walter B. Chase (*Medical Record*, September 2, 1916) states that the palliative influence of radium is analgesic, it inhibits or arrests malignant or benign growths, it diminishes or destroys offensive odors in local ulceration, it acts as a hemostatic in uterine hemorrhage. Chase cautions against the taking of a section of a cancer growth for diagnosis as it stimulates a more rapid development of the tumor. Epithelioma is more easily overcome than are most forms of cancer, while x ray cancer has been demonstrated to be curable by radium. The possibilities seem great for intravenous injection of radium salts and radium water or emanation in rheumatoid arthritis and in chronic neuritis with faulty metabolism. There is also seen an increase in red blood cells and hemoglobin, while blood pressure can be lowered permanently in many cases. Tuberculous glands and goitre show satisfactory cosmetic results when treated by radium. The use of hollow needles containing the radium effectually screened is applicable to tumors, both benign and malignant, particularly in the tongue, tonsils, and pharynx.

Alveolar Osteomyelitis (Pyorrhœa alveolaris): Its Causes and Treatment with Vaccines.—Leon S. Medalia (*Boston Medical and Surgical Journal*, September 14, 1916) concludes that pyorrhœa alveolaris should be known and treated as a chronic alveolar osteomyelitis. The sockets are enlarged medullary spaces of the maxillary bones, while the peridental membrane is in reality a ligament which keeps the tooth suspended in the alveolar cavity. Mechanical causes are responsible for starting the disease, while pyogenic bacteria, pneumococcus, staphylococcus, and M. catarrhalis, are responsible for keeping is up. It is a specific disease, though not in the sense that it is always due to one and the same organism. Systemic diseases play only a secondary part in starting the disease, but may be caused by it, and in turn become responsible for keeping up the local condition. Many rheumatic diseases, so called, and many gastrointestinal diseases are directly related to Riggs's disease, as this affection is often known. Vaccine treatment, together with proper attention to diet, cures or relieves the systemic diseases, especially the rheumatic affections. Local mechanical treatment and proper attention to the general systemic condition of the patient yield by far the best results in this intractable disease.

Treatment of Ulcerating Carcinoma.—J. Tugendreich (*Berlin. klin. Woch.*, March 6, 1916) states that none of the large number of drugs so far recommended for the treatment of carcinomatous ulceration, has proved of any great value, even solely for the relief of symptoms. The recent exhaustive studies of Morgenroth on the derivatives of quinine have led to the production of several compounds, which combine the properties of producing prolonged anesthesia and marked antiseptic power with low toxicity. On the strength of these researches, the author tried the local application of one of these substances—isoamylhydrocuprein—in a series of cases of ulcerating carcinoma which had proved resistant to other measures. The results were favorable, the drug producing prolonged anesthesia with complete relief of pain, and cleansing the surface so that healing and epithelialization frequently occurred. He used solutions of the base in olive oil varying from one to two per cent., or oily suspensions of the hydrochloride of the same strengths.

Emetine Bismuth Iodide in Entamœba histolytica Infection.—George C. Low and Clifford Dobell (*Lancet*, Aug. 19, 1916), following Dale's favorable experience with this new insoluble emetine salt, tried it in several refractory cases of amebic dysentery and carriers thereof. They report three typical cases. They gave the drug in single daily oral doses of 0.2 gram following the evening meal. In acute cases it proved equally effective with emetine subcutaneously, and in carriers seemed more effective than the soluble salts. One chronic convalescent carrier was apparently cured after the fourth dose, and another normal carrier, not previously ill with clinical dysentery, showed equally prompt disappearance of the cysts. Contrary to Dale's experience the authors found the preparation likely to produce some nausea, vomiting or diarrhea after a few doses, to an extent almost equal in several cases to that caused by the oral use of ipecac, but usually only to a much less degree.

Intravenous Injection of Oxygen Gas.—F. W. Tunnicliffe and G. F. Stebbing (*Lancet*, Aug. 19, 1916) have noted beneficial effects of oxygenated saline solution for intravenous injection and that animal experiments had previously proved the safety of slow injections of oxygen gas directly into a vein, and have been led to try such injections in man for the relief of a number of forms of cyanosis. They found it possible, by means of a needle and a simple supply apparatus, to inject safely pure, washed oxygen gas at the rate of 600 to 1,200 mils an hour. During the injections the heart was auscultated frequently and the one dangerous sign was found to be the appearance of a soft, systolic tricuspid murmur. From time to time the rate of injection had to be slowed temporarily, but the gas was never quite stopped on account of the danger of clotting. The injections were found to be of decided therapeutic value in all forms of cyanosis, except those secondary to severe cardiac disease. The effects were also found to be fairly lasting in most cases, and often were so striking as to proves actually life saving.

Cheiropompholyx.—P. G. Unna (*Berlin. klin. Woch.,* March 6, 1916) considers that this condition is probably infectious in origin. Its cure requires the use of antiseptics, as well as measures to allay the intolerable itching. The parts should be bathed in warm soap solution, after the small vesicles have been pricked or the tops of the large ones have been cut off with a razor. To secure penetration of the disinfectant it should be dissolved in alcohol rather than in water or oil. The following formula provides an excellent application which can be painted over the affected parts:

℞ Argenti nitratis, ...1.5;
Spiritus ætheris nitrosi, ...30.0.
M. Dispense in a brown bottle.

The Causation of Gastric and Duodenal Ulcer by Streptococci.—E. C. Rosenow (*Journal of Infectious Diseases,* September, 1916), in a previous article, has shown that a local hematogenous streptococcal infection is the usual cause of ulcer of the stomach. The present experiments were undertaken to prove that the streptococci isolated from the ulcer wall produce, when injected into animals under otherwise normal conditions, ulcers of the stomach and of the duodenum resembling those in man. His results are reported in this article and they substantiate his statements. The ulcers that were produced by the injection of streptococci resemble those in man in location, in gross and microscopic appearance, and in that they tend to become chronic, to perforate, and to cause severe or fatal hemorrhage.

Use of Emetine.—Alfred C. Reed (*Boston Medical and Surgical Journal,* September 14, 1916) gives a summary of the history, pharmacology, and toxicology of emetine, and discusses its uses. Its predominant use is in the treatment of amebic dysentery, in which it seems to be specific in direct proportion to the acuteness of the attack. Benefit will usually appear early, ordinarily by the third or fourth day, if at all. It must be supported by symptomatic treatment, such as correct diet, catharsis, and rest. Chronic dysentery and carriers are not influenced directly by emetine as a rule. Emetine has very definite use in the presuppurative stage of amebic abscess of the liver, and after actual abscess formation, it may be a valuable adjunct to the surgical treatment, particularly when the abscess has ruptured and spread amebas through the contiguous tissues. It cannot be said that emetine is a specific for pyorrhea, that emetine alone will cure it, or that it cannot be cured without the use of this drug. The same is true of other bony and oral abccesses and infections, but given the pathogenic ameba, emetine is the specific remedy, provided that the infective agent is not walled off in an abscess. In so far as emetine excites a mild nausea, it shares the action of ipecac as an expectorant. It has been lauded as almost a specific for hemorrhage in certain chronic disease, especially for hemoptysis in pulmonary hemorrhage, but there is no experimental evidence that it has the slightest influence on hemorrhage directly, or that under any circumstances it promotes coagulation. Emetine lowers the blood pressure, weakens the heart, and depresses the central nervous system. Whatever beneficial action in tuberculosis it has would seem to be due to its expectorant properties, but even so, other preparations are preferable. A beneficial action in hemorrhage may be due to the indirect result of decreasing blood pressure, yet if so, other drugs would be safer and more effective. The use of emetine enemata for constipation does not seem to be well advised. Emetine has proved serviceable in the treatment of certain other diseases caused by animal parasites, especially protozoa, but its main uses are due to its amebicidal action.

Peripheral Neuritis Following Emetine Treatment of Amebic Dysentery.—A. R. Kilgore (*Boston Medical and Surgical Journal,* September 14, 1916) reports several cases of this nature, and goes on to say that peripheral neuritis after emetine is not uncommon. The common symptoms are generally muscular pain and weakness, usually most pronounced in the legs, going on sometimes to paresis. They often appear after the emetine injections have been stopped, and may grow progressively worse for some time, even with no more administration of the drug. The amount of emetine necessary to produce neuritis varies greatly. The prognosis is good. The symptoms clear up gradually, usually over several weeks, and apparently no traces are left.

Alkaloidal Adjuvants in General Anesthesia.—Raymond C. Coburn (*Medical Record,* Sept. 9, 1916) advises the preliminary administration of morphine one sixth to one quarter grain to an adult, with the addition of atropine grain 1/150 if nitrous oxide is to be used. If ether is to be used, atropine is not essential, though advisable. Scopolamine, 1/200 grain, may be combined with one sixth grain morphine one hour before operation, whereas if morphine and atropine alone are used they should be given one half hour prior to operation. Nerve blocking as advised by Crile diminishes shock and consists in infiltration of the skin and the subsequent layers of the incision with twenty-five per cent. solution of novocaine, and then in some cases the deeper layers away from the incision with one sixth per cent. of quinine urea hydrochloride. Nitrous oxide is the best anesthetic to use in conjunction with alkaloidal adjuvants.

Drug Intoxication.—Edward Livingston Hunt (*Western Medical Times,* September, 1916) urges that great care should be exercised in the administration of sedatives for the purpose of producing sleep. If, at the end of two or three days, no improvement results, a complete change of treatment should be inaugurated, all drugs being stopped. All mental conditions showing symptoms of confusion, delusions, fabrications, restlessness, and violence, coincident with a rapid pulse, and such physical signs as a coated tongue, low temperature, and emaciation, should be regarded with suspicion as being possible cases of drug intoxication. In all prolonged illnesses in which the use of many drugs has become a necessity, a sharp outlook should always be kept for symptoms of drug intoxication. Patients who present functional conditions or any physical condition below par should avoid drugs. Physicians should use greater discrimination in the use of bromides. Finally, conditions of drug intoxication should be considered as of more than ordinary occurrence.

Simple Dressing for Fractures Near the Elbow.—Louis C. Rivett (*Brit. Med. Jour.*, Aug. 19, 1916) remarks that the difficulties in keeping the arm in proper position and the practice of smothering the entire chest in dressings are overcome by the following simple technic. The forearm is flexed on the arm and held in this position by a single strip of two inch adhesive plaster, placed near the wrist and at the level of the deltoid insertion. A second strip is attached to the back of the wrist and hand and passed over the shoulder and some distance down the back. No other dressing is applied. Excellent results have followed this form of dressing and it has the great advantage of permitting abduction of the elbow for x ray examination without disturbing the position of the fragments or touching the dressing.

Hemoglobinuric Fever. — William O. Ott (*Jour. A. M. A.*, Sept. 16, 1916) records the case of a patient who had malaria, for which he had been taking quinine by mouth without relief. He then suffered from a severe attack of hemoglobinuria with vomiting, and was thought to be moribund when it was determined to try the effects of quinine intravenously. This was given in the form of the dihydrochloride in a dose of six tenths gram dissolved in 300 mils of saline solution. The first dose was followed in a few hours by some alleviation of symptoms and the drug was therefore repeated. Six doses were given, three on the first, two on the second and one on the third day. All symptoms promptly disappeared and from the fourth day on the patient was given quinine orally. Recovery was complete and the patient was well and free from malarial symptoms when heard from two months after treatment.

Salt Pack Treatment of Infected Wounds.—J. E. H. Roberts and R. S. S. Statham (*Brit. Med. Jour.*, Aug. 26, 1916) find that before the application of this form of treatment it is necessary to be sure that the wound is freely open in its entire extent, and when such is not the case it must be brought about by suitable incisions. A second essential preliminary is the excision of all badly torn and contused tissue, since this does not enter into the healing process, but dies and delays the granulation. The skin is then painted with iodine and the wound cleansed without any antiseptic and mopped dry. Four or five layers of plain gauze are next wrung out of a five per cent. saline solution and used to line the entire surface of the cavity and all of its recesses. The lining must be in the form of a single sheet of gauze, not of several overlapping small pieces, and no spaces must be left between the gauze and the cavity walls. A few two and a half grain tablets of salt are then placed within the gauze, and the cavity is firmly packed with a strip of gauze moistened in five per cent. saline, several more tablets of salt being placed between the layers of the packing. When the packing is flush with the skin it is covered with a few layers of gauze and over all a thick wool dressing is applied to completely encircle the extremity. This is then bandaged with firm pressure to maintain the complete obliteration of all cavities. This dressing can usually be left in place for five or six days, depending upon the patient's general condition and the rate of his pulse, which is the best guide to septic absorption. If the pulse rate rises the dressing should be changed, but the mere saturation of the dressing with serum is no indication for a change even if the secretions become foul. In the latter case the outside of the dressing may be treated with eupad or chloramine T powder. The first dressing is usually quite painful and a dose of sixteen mgm. of morphine should follow its application. Subsequent dressings are progressively less painful. Usually from the tenth to the twentieth day the gauze lining will come away leaving a bright red, healthy granulating surface and the wound can be closed either by suture, or by adhesive strips.

The Fourth Disease.—Edwardo Donetti (*Riforma medica*, August 21, 1916) reports fifteen cases and concluded that Dukes's or Filatow's disease is a definite entity with classical periods of incubation, invasion, eruption and desquamation. The incubation period is from two to eight days, while that of invasion is characterized by an angina which may be simple or follicular with enlargement of the cervical glands, a temperature of not more than 38.5° C. due to the pharyngitis and following the course of the throat condition. The period of eruption appears not more than forty-eight hours later with a superficial reddening of the entire skin, with simultaneous formation of small punctiform papules which remain four to five days. The fever persists only during the first and second days. The desquamation is rapid, branny in character with sheetlike peeling of the hands and especially the fingers, and pruritus is common. There are never complications in the kidneys or respiratory organs, though there may be slow resolution of the cervical and submaxillary glands, late pharyngitis and general depression. The disease has no predilection for seasons and is epidemic and contagious.

Treatment of Ankylostomiasis.—R. D. Keith (*Journal of Tropical Medicine and Hygiene*, June 1, 1916) asserts that at an early stage in hookworm disease any of the anthelmintics ordinarily recommended prove efficient. In later cases, with grave anemia, oil of chenopodium is the best remedy. Keith found it more efficient than any of the others in obstinate cases, giving it in thirty minim doses in an emulsion every hour for three hours on an empty stomach. One hour after the last dose two ounces of black draught are given. In thirty cases the author used a vaccine made from the triturated bodies of adult hookworms placed alive in absolute alcohol, then evaporated almost to dryness and made into an emulsion with saline solution; the method, however, was found devoid of value. In severe cases of a chronic type in which the bone marrow may have become exhausted and atrophic, hypodermic administration of iron and arsenic has been recommended. A good diet assists materially in improving the blood. In native coolies suffering from the effects of the disease Keith found the following daily diet very useful: Bread, one pound; milk, two pints; sugar, two ounces; two eggs, and four bananas.

Auricular Standstill: An Unusual Effect of Digitalis on the Heart, with Especial Reference to the Electrocardiogram.—Paul D. White (*Boston Medical and Surgical Journal,* August 17, 1916) describes three cases in which electrocardiographic evidence of auricular actiyity was abolished by digitalis. As soon as the effects of the digitalis had worn off the auricular deflections reappeared.

Human Sporotrichosis.—E. S. Tyau (*China Medical Journal,* July) reports a case of this nature in which external application of Lugol's solution with administration of increasing doses of potassium iodide produced great improvement in ten days. Cultures from the open sore were then taken and no fungus was found. This course of treatment was followed for eight weeks and resulted in complete recovery.

Restoration of the Nose by Cartilage Transplantation.—Péraire, at a meeting of the Société de médecine de Paris (*Presse médicale,* July 6, 1916), presented a man whose nose had been completely carried away by a shell fragment eighteen months before. Transplantation of the seventh costal cartilage to replace it had yielded an excellent result, and the transplant had undergone no absorption during that prolonged period.

Staphylococcus Spray in Diphtheria Carriers' Throats.—Felice Lanzarini (*Gazzetta degli ospedali e delle cliniche,* August 13, 1916), after extensive experiments, found that the pyogenic organisms inhibited the growth of the diphtheria bacillus, not so much from a true antagonistic action, but rather from a crowding out or starving out process, since these pyogenic organisms grow much faster and under much more unfavorable conditions.

The Bacteriology of the Urine in Lobar Pneumonia.—Mathers (*Journal of Infectious Diseases,* September, 1916), as a result of careful bacteriological examination, found living pneumococci in the urine of ten out of twenty-six patients with lobar pneumonia. In eight others, Gram positive diplococci were present, but the cultures were negative for pneumococci. The organism appeared in the urine usually just before or just after the crisis.

Potassium Permanganate in Cutaneous Infections.—Edmundo Escomel (*Cronica Medica,* of Lima, August, 1916) is enthusiastic concerning the use of moist dressings of saturated solution of permanganate in many varieties of skin infections including boils, erysipelas, and even cellulitis of the hand or foot. Its action is astringent, antimicrobic, and oxidizing, and its toxicity is so weak that it never causes any symptoms from absorption by raw surfaces.

Treatment of Pellagra.—J. Yarbrough (*Medical Record,* September 2d, 1916) insists that the disease is due to fermentation of carbohydrate food and that there should be immediate and complete exclusion of such carbohydrates from the diet. This dietetic measure should be combined with dilute nitric acid—twenty to thirty drops in a glass of water an hour before meals. Of over one hundred cases so treated none required more than four weeks to clear up, in the absence of complications.

Eclampsia, a Preventable Disease.—John W. Winston (*Medical Record,* September 2d, 1916) lays great stress on the importance of the blood pressure test, which he places ahead of uranalysis. A systolic pressure below 125 mm. may be disregarded. One from 125 to 150 mm. needs watching and careful treatment. An increasing pressure of 150 mm. is of more serious portent than one which has been 150 mm. from the start. A pressure above 150 mm. needs active eliminative treatment, and, if it goes steadily higher, may require the induction of premature labor. A rising blood pressure curve is a better index of the toxemia than the albuminuria, and it occurs earlier.

Treatment of Tuberculosis by Ferran's Nontoxic Vaccines.—V. Santini (*Cronica Medica,* July 25th, 1916) asserts that the soluble inflammatory and diffusible toxin, which constitutes the true tuberculosis poison, is capable of producing the reaction of antibodies to the exclusion of the colloid toxin, which is produced only by the bacillus when it has acquired new properties in its symbiotic life. Filtered bouillon cultures, while not free from colloidal toxins, nevertheless of all the tuberculins are the least impregnated with these substances, therefore Ferran's is to be preferred. Over two hundred cases, treated with these atoxic bacterins, stood the treatment well and were uniformly benefited thereby.

Pyorrhœa alveolaris. — Beverley Robinson (*American Medicine,* August, 1916) regards the treatment with emetine of value only in exceptional cases. He advises dental instrumentation and the use of Augustus B. Wadsworth's mouth wash three or four times daily over a period of months. The wash should be kept in the mouth for from three to five minutes. It should be diluted with two to four parts of water. Attention should be paid to the general health and diet. Internally, occasional doses of castor oil should be given and Bacillus bulgaricus in pure culture should be taken regularly for many months. If the origin of the disease is obscure an x ray picture should be taken.

General Principles of Bone Grafting.—C. A. McWilliams (*Medical Record,* Sept. 16, 1916) enumerates the general principles to be observed in this field of surgery. Briefly they include scrupulous asepsis, awaiting the healing of sinuses before operating, the use if possible of autogenous grafts with as much periosteum as possible, greatest possible hemostasis, and absence of drains. Further all foreign nonabsorbable material should be avoided if possible, absolute immobilization is essential, and grafts need fill defects vertically only as the lateral deficiency would be filled out by nature. It is important to prepare the bed for the graft, and then to place the graft therein as quickly as possible and inlay grafts are preferred to the intramedullary splint. The site from which the graft is obtained varies, the tibia being preferred by most surgeons, with the fibula next in order, while in a few cases grafts have been taken from ribs, clavicle, crest of the ilium, scapula, and bones of the hands and feet.

Miscellany from Home and Foreign Journals

Gluteal Fold in Sciatic Neuritis.—Hildred Carlill (*Lancet*, August 19, 1916) has noted a diagnostic sign of considerable importance, which had apparently escaped observation. It consisted of a flattening or disappearance of the normal gluteal fold during full extension of the thigh on the affected side. This was found to occur in cases of sciatic neuritis, when the entire nerve trunk was involved or when the fibres from the fifth lumbar and first and second sacral roots were affected. When taken alone it did not indicate the extent of the sciatic involvement, but when present in association with loss of the ankle jerk it indicated the involvement of the whole sciatic trunk. As yet an insufficient number of cases has been observed for this gluteal sign to define its exact importance.

The Gastrointestinal Tract in Diabetes.—James T. Case (*Jour. A. M. A.*, Sept. 16, 1916) reports seventy-two diabetics subjected to most painstaking and thorough röntgenological examinations of their alimentary canals. The examinations showed that involvement of the gallbladder, especially in lesions producing pericystic adhesions, was common; that the stomach emptied itself with abnormal rapidity, which was to be expected from the low acidity of the gastric juice in diabetes; that, contrary to the opinions of others, duodenal stasis was rare; that ileac stasis was common and bore a striking relation in its severity to the severity of the diabetes; that incompetency of the ileocecal valve was common; and finally, that most patients had a moderate degree of colonic stasis.

Marriage and Cardiac Disease in Women.—A. P. Cabrera (*Revista de Medicina y Cirugia Practicas*, August 7, 1916) reiterates the manifesto of Peter that if a woman with organic heart disease is single she should not marry, that if she marries she should not conceive, and if she bears a child she should not nurse it from the breast. Romberg maintains that such women should be forbidden to marry and Cabrera maintains that the law should interfere to prevent such marriages. Pregnancy almost inevitably destroys compensation in cardiac cases, and when premature labor becomes imperative the slower methods are of no avail and Cæsarean section offers the only hope of saving the child, while the maternal prognosis is extremely grave.

Action of Guanidin on the Circulation.—E. I. Sinelnikova and M. P. Bovshik (*Roussky Vratch*, June 4, 1916) investigated the effect on the circulation of guanidin, an end product of nitrogen metabolism, similar to creatin. In the experiments performed on dogs, cats, and rabbits it was found that 0.005 gram per kilogram weight, injected intravenously, caused a transient fall and then a prolonged rise of blood pressure to the extent of twenty to fifty per cent., and slowing of heart's action forty-seven per cent. The action is apparently due to the stimulation of centres of the pneumogastric in the medulla, as well as the effect of guanidin on the peripheral nerves and muscular elements of the vessel walls.

The Heart in Active Service.—H. J. Seeuwen (*Jour. A. M. A.*, September 9, 1916) found twenty per cent. of the cases to be in wounded men; twenty-five per cent. of the patients were debilitated from infections, such as sore throat, dysentery, typhoid, etc., and in over half of the patients evidence of long standing cardiac weakness was obtainable. Only ten per cent. of the men under observation had been athletes. The role of bad teeth seemed to be important, for only eight of sixty men had healthy, clean dentures. One quarter of the whole number showed evidence of thyroid hypertrophy which was thought to have more or less direct relation to the presence of infection. Alcohol and tobacco seemed to play minor roles. These men were given graded exercise, and faradic current over the heart and thyroid gland; as a result more than one third were able to resume arduous work in about two months and only ten to fifteen per cent. required discharge from all military duty.

New Data on Periodical Activity of the Digestive Tract.—A. I. Nikulin (*Roussky Vratch*, June 4, 1916) by experiments on dogs with artificial fistulas communicating with the salivary glands, stomach, and duodenum, determined the effect of various substances on the periodical activity of these organs. He found that function was inhibited by any acid introduced into the duodenum, by pain, particularly in the small intestines, and by raising the temperature of the body. Occasional inhibition was produced by the introduction into the duodenum of large quantities of such indifferent substances as water, liquid petrolatum, and egg albumin. If the temperature of the liquid was very high or very low inhibition was induced, unless the liquid was thrown into the stomach by an antiperistaltic wave. The inhibition was more marked and was more rapidly produced when the digestive organs were in apathological condition such as acute gastrointestinal catarrh. High body temperature diminished gastric contractions, while low temperature increased them.

Value of Ileosigmoidostomy in Arthritis.—John T. Bottomley (*Jour. A. M. A.*, September 9, 1916) has brought together the results secured by others and those in the author's own series of patients, in order to throw light on the value and limitations of colectomy and ileosigmoidostomy in cases of chronic arthritis. Of a total of twenty-nine cases twelve were cured or greatly improved, four were considerably benefited, eleven were unchanged or were worse, and two were fatal, but not as a direct result of the operation. In nearly all cases there was decided improvement beginning almost immediately after the operation, but in many this was only transitory and the arthritis resumed its progressive character. The operation should be restricted to cases in which colonic stasis and infection seem to be the prime causes of the arthritis, all other sources of infection or toxic absorption having been satisfactorily eliminated. Colectomy would seem to be preferable to ileosigmoidostomy on account of the higher proportion of good results which follow its performance.

Education Through Posture—An Opportunity for the Orthopedist.—Joel E. Goldthwait (*American Journal of Orthopedic Surgery*, August, 1916) makes a plea for preventive medicine by early and proper training in children to prevent poor and faulty postures which might bring on subsequent chronic diseases. He quotes many keen observations, along this line, made by M. André in 1741.

Study of the Boas-Oppler Bacillus.—P. G. Heineman and E. E. Ecker (*Journal of Bacteriology*, July, 1916) as a result of their investigations of gastric juice conclude that the Boas-Oppler bacillus belongs to the group of lactic acid bacilli which occurs frequently in foods, chiefly milk. Its presence in large numbers in the gastric juice is an indication, merely, of a reduction in the normal hydrochloric acid content, whether this is due to gastric ulcer, gastritis, pernicious anemia, or gastric carcinoma, or possibly to other pathological conditions.

Effect of Adding Fresh Human Serum to Artificial Media.—Leonard S. Dudgeon, F. Bawtree, and Dudley Corbett (*Lancet*, August 19, 1916), prompted by the observation that bacterial growth was often apparently stimulated by the presence of human exudates in the media, have conducted a series of observations to determine the effect of normal blood serum. They found that the addition of such serum to fluid or solid media greatly increased the growth of many pathogenic organisms, while nonpathogenic ones were not similarly stimulated. It yielded positive cultures where other methods failed and greatly prolonged the growth of those organisms which tended to die out in artificial culture. It facilitated the growth of diphtheria, meningitic and pneumonic organisms very markedly, and materially altered their morphology in the direction of that normally found in fresh smears. In fluid media it provided an excellent means of securing abundant growths for the preparation of vaccines. The results recorded were secured with unheated serum, the heating having been shown to deprive it of many of its advantages.

Relation of Cecal Stasis to Dementia præcox.—Bayard Holmes and Julius Retinger (*Lancet-Clinic*, August 12, 1916) had previously shown that the toxic amines, especially betaiminazolylethylamine (histamine), produce reactions resembling many of the symptoms of dementia præcox. They now report having found definite evidences of an intoxication with these amines in the blood, urine, and stools of dementia præcox patients. Thus, from 0.0005 to 0.005 gram of histamine in the 100 grams of moist feces was found in each of seven patients, six with dementia præcox and one with the gastric crises of tabes; on the other hand, all normal control subjects were negative as to histamine. Seeking an explanation for the presence of the toxic amines in the dementia præcox cases, the writers were led to study the motor functions of the intestinal tract in these patients by means of the barium meal and serial fluoroscopy. Whereas motility in the stomach and upper intestine was found normal, the tail of the barium residue was in every case still present in the cecum and proximal colon fifty-four hours after the ingestion of the meal. Opportunity for the development of the toxic amines from protein foods through bacterial action or otherwise, is thus afforded by the prolonged stay of the material in the cecum. This, in turn, is ascribed to a spasm of the sphincter which has been shown to exist at the junction of the first and middle thirds of the transverse colon, stagnation resulting in the proximal colon. The colon bacillus, grown under suitable conditions on media containing histidine—a product of protein decomposition—has itself been shown capable of producing the toxic histamine. Further researches are contemplated to elaborate rational therapeutic measures for dementia præcox based on the peculiar observations already made.

Direct and Indirect Hay Fever.—W. Scheppegrell (*Jour. A. M. A.*, Sept. 16, 1916), after an extensive study of pollens and of hay fever victims, would divide hay fever into two forms—direct and indirect. The direct form is due to spiculated pollens, the indirect to smooth or nonspiculated ones. A classification of pollens with reference to the presence or absence of spicules is given, and it shows, in general, that the nonspiculated varieties belong chiefly to the grasses and are the causes of the spring form of hay fever. The spiculated pollens are from the autumnal plants chiefly, among which the ragweeds are the commonest offenders. The spiculated pollens are very low in protein content and are so hard that they probably would not readily yield up what little protein they do contain. The converse is true of the smooth forms, which are rich in protein. The statement is made that the increased susceptibility to pollen is not due to anaphylaxis in the case of spiculated varieties, but is an increased local sensitiveness of the nasal mucosa to irritation by pollens as a whole.

Enteritis of Measles.—K. Secher (*Berlin. klin. Woch.*, March 6, 1916, remarks that several observers have noticed the symptoms of enteritis in measles, but, in general, the condition has been accorded little attention. Secher observed enteritis in thirteen out of thirty-one cases of measles, in two of which it resulted fatally. In every case the enteritic symptoms began nearly simultaneously with the outbreak of the exanthem. In six of the cases the enteritis was mild, with several watery movements daily for three to five days. In four cases mucus was present at times in the stools, and the enteritis persisted for two to three weeks. In one case it lasted for three months, and in two cases death came on the twenty-third and twenty-fourth day, respectively. At autopsy in these cases there were found infiltration of the mucosa of the lower ileum and marked hyperplasia of the solitary lymph follicles and of Peyer's patches. The mesenteric lymph nodes also showed hyperplasia. A few small submucous hemorrhages were found in the lower ileum, but ulceration was absent. This form of enteritis, beginning with or at once following the exanthem, was thought to be due to the measles virus itself, and it must be distinguished from the form which develops later at times and is due probably to secondary infection. The primary form may pass into the secondary by the occurrence of infection in the already damaged tissues.

Wassermann Reaction in Tuberculosis Cases.—W. Ray Jones (*Medical Record,* September 2, 1916) writes that of 251 dispensary cases unselected fourteen per cent. gave a three plus reaction, twenty per cent. a two plus or stronger and twenty-nine per cent. one plus or stronger. History, old scars, nerve signs and symptoms were strangely absent and it is an interesting question whether the weaker reactions were due to syphilis, or to tuberculosis as some hold.

Biological Action of the Röntgen Rays.—M. I. Memenoff (*Roussky Vratch,* July 2, 1916) established experimentally the fact that when the testicles are exposed to the action of the x rays the cells of Sartoli lose their secretory power, as shown by the absence of lipoid substances within the cells. On the other hand, the cells of Leidig assume increased growth, owing to increased nutrition. Contrary to the opinion of Wilms that the röntgenization of the testicles produces atrophy of the prostate, the author found that the latter undergoes hypertrophy. This he explains by the supposition that inasmuch as the cells of Leidig furnish the internal secretion which stimulates sexual activity, the increase of these cells leads to an enlargement of the prostate.

Organic Depression of the Nerve Cell from Prolonged Ether Anesthesia.—E. E. Butler (*Journal of Medical Research,* July, 1916) found that certain definite changes took place in the nerve cells of dogs after prolonged anesthesia. At first there were those indicative of mild activity, but later evidences of depression occurred, the severity depending upon the duration of the anesthesia. It was found that these changes of depression first made their appearance microscopically in about eight hours. A moderate depression resulted from an anesthesia lasting two to six hours—up to eight hours, a marked depression. A longer period caused profound depression with beginning destruction of the cell.

Trichinosis.—W. J. Cummins and G. R. Carson (*Jour. A. M. A.,* September 9, 1916) record observations made in fifteen cases which yielded the following information: The incubation period averaged three weeks; orbital edema was absent from one third of the cases; only one quarter had an eruption; four fifths were free from bronchitis; and not a patient in the series showed enlargement of the spleen. In eleven cases the pulse was slow to an extent out of proportion to the other symptoms. No trichinæ were found in either blood or feces, an embryo was found in the spinal fluid in one case of the twelve thus examined; the urine was free from parasites in all eleven cases in which it was examined, and the muscles showed parasites in eight of nine cases examined. Eosinophilia as high as seventy-five per cent. was encountered, but neither this nor the temperature or total leucocytosis bore any relation to the severity of the attack as indicated by clinical signs. An analysis of the observations suggested that the trichinæ pass through the veins in very small numbers, and in some cases not at all, owing to mechanical interference. The parasites also seemed to undergo partial or complete disintegration in the alimentary canal.

Dilatation of the Hepatic Flexure of the Colon.—W. J. Morrish (*Lancet,* August 19, 1916) reports a case of severe, chronic enterocolitis occurring in a young man on account of the occurrence of gaseous dilatation of the whole hepatic region of the colon. The dilated portion of the colon overlay the normal liver dullness and produced tympany, the coin sound and other physical signs of pneumothorax, subphrenic or hepatic abscess, or hydatid cyst. The correct diagnosis was possible only by radiography with and without bismuth, and was confirmed at a laparotomy and later at post mortem examination.

Ehrmann's Alcohol Test Meal.—A. da Silva Mello (*Berlin. klin. Woch.,* March 13, 1916) observes that this test meal consists of a draught of 300 mils of five per cent. ethyl alcohol containing 0.05 per cent. of sodium salicylate. It was tested in comparison with other test meals in a series of twenty-five cases and the following are the author's conclusions as to its merits: It has the advantage of being a solution of constant composition, readily prepared, palatable and easily taken; being fluid it can be withdrawn after half an hour through a very small tube, thus causing a minimum of discomfort to the patient; it is sterilizable, and is free from both albumin and acid. It stimulates the gastric mucosa independently of appetite. The results of titration which it gives correspond with those of the Ewald-Boas meal, but in contrast with the latter it yields a clear fluid in which macroscopic and microscopic contaminations are readily seen. Blood, bile and mucus from the esophagus can be easily determined quantitatively and, owing to constant stimulation of regurgitation from the duodenum, this meal can be used to measure biliary and pancreatic secretion. Finally, since it is free from bacteria, it is particularly suitable for studying the gastric flora.

Recognition of Gout as the Cause in Chronic Joint Affections.—W. Weinberger (*Archives of Diagnosis,* July, 1916) states that while recognition of gout is easy in cases with typical joint attacks and tophi, there are cases of atypical gout, with vague complaints and a chronic multiple joint involvement suggesting chronic rheumatism in which the bedside diagnosis may be difficult or impossible. The writer's clinical investigations showed that in such cases, among laboratory findings, chief reliance is to be placed in observation of the characteristic curve of uric acid elimination during an attack, whether this attack has occurred spontaneously or been artificially induced by ingestion of a definite amount of purin, e. g., ten grams of sodium nucleinate. The uric acid curve in the urine (Folin-Shaffer method) shows often a preliminary stage of depression—the anacritical depression stage of His; with the development of the attack it rises abruptly—Pfeiffer's uric acid flood—later again descending, this time below the original level—the postcritical depression stage of Umber. Following ingestion of purin an exacerbation of the joint pains takes place. Other laboratory findings in gout, such as high uricemia, low endogenous uric acid output, and delayed elmination of exogenous uric acid, are all too ambiguous or indistinct to be of decisive diagnostic value.

Axillary Temperature Determination.—P. Fürbringer (*Berlin. klin. Woch.,* March 13, 1916) states that almost from the very beginning of the practice of taking the human temperature in the axilla it has been recommended that the axilla should be wiped dry before inserting the thermometer. The basis for this recommendation is not apparent, but the author has carried out a large number of parallel readings in wiped and in moist axillæ and has found that in the great majority of cases, eighty-one per cent., the reading in the moist axilla was the higher. He concludes that this is more nearly a correct measure of the body temperature than the reading from the dried axilla. The use of the unwiped axilla has the further advantage of giving a more effective sealing of the space, of bringing the bulb into closer contact with the skin and of holding the thermometer more securely against slipping. Finally, in many cases the wiping actually accomplishes nothing, for the axilla becomes moist during retention of the thermometer.

Latent Tuberculosis. — Chung Yik Wang (*Lancet,* Sept. 2, 1916) states that lymphatic nodes from a group of patients clinically free from tuberculosis were tested by inoculation into guineapigs for the presence of living tubercle bacilli. The nodes were taken only from patients who had died and who showed no gross evidence of tuberculosis at autopsy. The nodes themselves, in every instance, were examined microscopically and found to be free from evidence of tubercle. A total of thirty-two cases were thus examined and the nodes from three were proved to contain living, pathogenic tubercle bacilli. A careful review of the literature showed that similar findings had been recorded by a few other workers, and when the results of all who had made such studies were included with those of the present series, they indicated that latent tuberculosis probably existed in an average of about twelve per cent. of human beings. It was impossible to determine the duration of such latency in the human being, but some observations which have been made upon guineapigs showed definite latency for as long as 104 days.

Early Diagnosis of Acute Infantile Paralysis. —L. C. Ager (*Archives of Diagnosis,* July, 1916) discusses the symptoms other than paralysis upon which an early tentative diagnosis may be based. The premonitory symptoms indicating an acute general infection vary as widely as in scarlet fever. The impression that has arisen, that catarrhal symptoms are frequent, is erroneous, increased secretions from the mouth, nose, and eyes being practically never present except in the later stages of severe infection. The existence of a large class of cases in which there is definite evidence of invasion of the central nervous system without an appreciable resulting paralysis renders it necessary that a tentative diagnosis be regularly proved or disproved by careful examination of the spinal fluid. The early diagnostic symptoms are divided by Ager into those of the psychic, the motor, and the sensory tracts. Characteristic is a psychic inhibition varying from drowsiness to coma. The latter is distinguished from that of meningitis in that the patient can be aroused to almost normal mentality; the special senses respond readily. Some children, however, exhibit a marked excitability and suspicious watchfulness; in a few instances, a state of delirium is reached. Among the early motor symptoms an anteroposterior cervical stiffness, usually with similar spinal rigidity, is frequent; a tendency to resist motion of any or all extremities may also be noted. Later, particularly in the meningitic type of case, there may be true—not reflex—spastic rigidity, scaphoid abdomen, and convulsions, as in other forms of meningitis. Occasionally increased knee jerk and ankle clonus are noted. The author has seen twitching of affected muscles before the advent of any definite signs of paralysis. The sensory symptoms, in the present epidemic, seem to be present in nearly every case. Pain and hyperesthesia are frequent in the polyneuritic—or better, pseudoneuritic—type of the disease. The pain and tenderness along the nerve trunk is usually such as to necessitate free use of codeine or morphine. Nearly always the skin and muscles of the back are similarly affected early in the disease, this being soon followed by muscular pain and tenderness in the limbs, often leading to treatment for rheumatism by mistake. Special centres are frequently affected in addition. Marked sweating even with a high temperature, is a frequent early symptom. Low temperature of a limb occasionally occurs early in the disease. Circulatory disturbance may be indicated by a tâche, irregular lividity or mottling, or pronounced localized flushing. To facilitate early diagnosis and permit helpful treatment, these symptoms as noted should be sought in all suspected cases.

Diagnosis of Enteric Fevers in Inoculated Persons.—Georges Dreyer and E. W. Ainley Walker (*Lancet,* Sept. 2, 1916) state that the agglutinin reaction is probably the most valuable means for diagnosing the several enteric fevers, but if the opinions of certain writers are to be accepted this test has lost much of its value since the practice of general inoculation was adopted. In the presence of the modifying factor of inoculation the agglutination test is just as trustworthy a diagnostic measure as in the noninoculated, but it must be made accurately quantitative and diagnosis must be based upon the comparative results of two or three successive reactions made at intervals of several days. From their very extensive experience of the reaction, as carried out quantitatively and with a standardized agglutinable culture, the authors found that the maximum agglutination titre of active typhoid or paratyphoid infection occurred between the sixteenth and twenty-fourth days of the disease. If the maximum is found before this time, a careful inquiry as to the exact date of onset is required. A diagnosis of one of the enteric fevers cannot be made from a moderate rise in agglutination titre if the maximum is found to fall certainly outside of the normal time limits, since such a rise may be due to other febrile conditions. Unless the several titrations be taken fairly near together one may miss the maximum and obtain two readings nearly alike in the presence of active infection. If there is a regular rise and later fall in the titre, even of only moderate extent, occurring within the normal limits, the diagnosis of typhoid or paratyphoid fever may be made even in persons with mild or atypical attacks.

Proceedings of National and Local Societies

THE AMERICAN ASSOCIATION OF IMMUNOLOGISTS.

Third Annual Meeting, Held at Washington, D. C., May 11 and 12, 1916.

The President, Dr. J. W. Jobling, of Nashville, Tenn., in the Chair.

(*Continued from page 619.*)

Inadequacy of the Anaphylatoxin Theory of Anaphylaxis (*Continued*).—Dr. Richard Weil said further that in these respects it was perfectly analogous to the anaphylactic reaction. If in place of the visible alteration, expressed as precipitation in the test tube, interaction of the two factors *in vivo* was supposed to produce an alteration of cellular equilibrium, such as would act as a cellular stimulus, all the requirements of the problem were satisfied. In view of the fact that precipitin had been demonstrated to be identical with the sensitizing antibody, this explanation of anaphylaxis seemed almost self evident. This conception rid them of the necessity of postulating an intermediate chemical product, namely, anaphylatoxin; such a postulate was not only superfluous, but was also entirely incompatible with all the characteristic features of the reaction.

The preceding discussion was limited to phenomena ascertained in guineapigs. Anaphylatoxin had been produced only through the incubation of guineapig serum. Yet in the guineapig the conclusion seemed unavoidable that anaphylactic death was due to a cellular reaction, and that the serum changes played no role therein. There was no question, on the other hand, that during the prolonged or delayed shock of the dog, striking alterations occurred in the chemical composition of the blood. These changes were due in the first instance to the freeing of protease, as a result of the reaction of the sensitized cells to the antigen. It still remained to determine whether the changes in the serum produced through the activity of the protease were really the cause of the later symptoms, or mere accompaniments of the shock in this species. Even in the former event, the primary step in the entire reaction, namely, the discharge of protease, would be cellular.

Specific Character of Immunity Reactions.—Dr. E. C. L. Miller, of Richmond, Virginia, believed that ordinary immunity reactions might be considered as a result of training. A horse to produce diphtheria antitoxin must have been injected with diphtheria toxin, a child to be immune to scarlet fever must have had scarlet fever. This immunity was specific. The horse that had been injected with diphtheria toxin produced diphtheria antitoxin and not tetanus antitoxin; the child that had recovered from scarlet fever was immune to scarlet fever and not to measles. All their thinking about immunity was based on the assumption that the relation of antigen to antibody was specific. Medicolegal tests for blood had been worked out and accepted by the courts on the assumption that only one antigen could react with the same antibody. Now, however, there was evidence that this was not true, that two or more antigens might produce the same antibody and that the same antigen might produce two or more antibodies. This had been particularly well demonstrated in the hemolysis of the red blood cells of sheep. It had been shown by a number of workers that a specific sheep hemolysin could be produced in a rabbit, not only by the injection of sheep blood cells, but also by the injection of such entirely unrelated substances as the liver of the guineapig, the gills of a carp, or the kidneys of a turtle. The explanation of this seemed to be that the relation of antigen to antibody did not depend on the entire protein molecule as a whole, but rather on certain groups in the molecule, and it so happened that various unrelated substances contained these groups and so produced a common antibody.

Dr. H. Gideon Wells, of Chicago, stated that in all problems of immunology, specificity was the vital point which could never be overlooked without disaster. Nevertheless, many hypotheses had been developed which entirely disregarded specificity, and, therefore, must obviously be incorrect. In studying the principles of immunology, there had been great difficulties because of the failure to grasp the essential principles, as laid down by Jacques Loeb—that in studying the fundamental principles of biological processes they must reduce the elements involved to the simplest possible, for at the best the reactions were complex and difficult of interpretation. It would be recalled that he reduced the factors in his reactions to the simplest possible, by using the single egg as a living organism and the simple inorganic salts as his agents. In studying the principles of immunology they should follow these principles as far as possible. Unfortunately, they apparently could not get below the whole protein molecule as one end of their reactions, and generally must use the warm blooded mammals for the other side of the equation, although possibly work on cell cultures might help them to simplify their materials.

The best they could do, therefore, was to use pure protein, and, fortunately, there were some proteins that could be obtained in relatively pure condition. Those proteins which differed greatly from the great majority of proteins, were especially favorable materials for purification, such as noncoagulable ovomucoid of egg white or alcohol soluble proteins of the grains. Using such isolated proteins, and others, they had found evidence that, delicate as the specificity of immunological reactions seemed to be, immunological differences did not seem to occur between proteins that could not also be differentiated chemically. The specificity differences of the different proteins seemed to agree with differences in chemical composition, and, as yet, they had not found finer differences, such as stereoisomeric differences with identical chemical composition.

To illustrate: By comparative study of different proteins isolated from hen's egg by anaphylaxis, the speaker had been able to distinguish five proteins definitely distinguishable from one another by this

means. Osborne and Harris, working by chemical means, isolated from the hen's egg five different proteins which corresponded exactly to the five antigens differentiated by anaphylaxis. Proteins of the egg that could not be differentiated by chemistry could not be differentiated by anaphylaxis. Doctor Osborne and the speaker had also found in many cases that proteins which were isolated by chemical means could be checked up accurately as to their individuality by anaphylaxis and other immunological reactions, and immunological methods had been found to be of much help in establishing the chemical identity of unknown proteins.

Dr. John A. Kolmer, of Philadelphia, said that it would be difficult to improve upon the excellent summary presented by Doctor Jobling on the relation of lipoids to immunity. He agreed with the essayist that more and more importance was being attached to the role of lipoids in this field. It had been amply proved that a toxic substance might be prepared of various animal and vegetable proteins by the method employed by Doctor Vaughan; likewise toxic substances could be produced in normal and immune serums by the addition of such substances as kaolin and agar capable of producing anaphylacticlike symptoms and lesions in experimental animals, but it was not yet clear what relation these observations bore to the mechanism of anaphylaxis and particularly so in view of the work presented by Doctor Novy within the past few days. He asked Doctor Vaughan if he was prepared to make any further statement in regard to the relation between his protein poison and the mechanism of anaphylaxis. He asked Doctor Miller if he had made careful titrations of the content of antisheep hemolysin in the serums of his rabbits before immunization, as the serums of a large proportion of these animals contained natural antisheep hemolysin. In his opinion, "group reactions" in immunity were best explained at the present time according to the views expressed by Doctor Wells.

Doctor Vaughan had watched Doctor Novy's experiments with the deepest interest. Even before Doctor Novy spoke to him about it, he had observed the appearing and disappearing and reappearing wave of toxicity in serums being incubated with agar and other foreign bodies. He spent much time and sacrificed many animals in trying to measure these waves and catch the rhythm of the toxicity, but without results. He was not yet ready to abandon the idea that a protein poison was formed in anaphylactic shock. No one could tell whether this was due to a chemical or physical process. It was difficult to draw a line between physical and chemical changes. He could conceive that a body so complex as the protein molecule might be dissociated and a poisonous action developed even by high dilution. If so stable a body as sodium chloride could be broken up into its ions by dilution, was it not possible that even more marked alterations might occur in a highly complex molecule? He was convinced of the fact that the blood contained proteins from which a poisonous group was easily detached. Doctor Novy had accumulated many experimental data. He hoped that he would soon publish his protocols and give them all an opportunity to try their hand at theory and explanation.

Dr. James W. Jobling, of Nashville, Tenn., stated that the intoxicating dose in anaphylaxis probably acted first on the cells. In guineapigs it caused a contraction of the muscle cells of the bronchi to such a degree that immediate death ensued from asphyxia. In dogs, however, death did not occur for several hours, and the clinical picture was quite different. In the latter case they had observed definite changes in the blood, and believed that death was probably due to the products of protein cleavage. The ferments, which were greatly increased in amount, were probably liberated as a result of the cell stimulation, and their activity was dependent upon colloidal changes which had taken place when the antigen was brought into contact with the serum. They observed a definite increase in the higher and lower protein cleavage products in the blood. These, they believed, were derived from the serum proteins and not from those introduced.

Dr. Richard Weil, of New York, was not particularly interested in establishing the universal validity of any of the current theories of anaphylaxis. Attempts of this sort had done more in the past to obscure the truth than to advance it. For example, the discovery by Friedberger that anaphylatoxin could be produced in the test tube led at once to the assumption that such a substance was produced *in vivo* and was the actual cause of death in the guineapig; consequently the German school expended a great deal of labor to overthrow the cellular theory of anaphylaxis in the guineapig and to establish the humoral theory in order to vindicate the truth of the primary assumption. Time, however, had completely established the truth of the cellular theory, so that in the guineapig, at all events, it seemed certain that serum changes, with the production of so called anaphylatoxin, could play no role in the typical evolution of shock. It would, however, be just as serious a mistake to assume that the process which took place in the guineapig must necessarily be universally applicable to the anaphylactic phenomenon throughout the animal kingdom. They knew that between the guineapig and the dog, for example, certain striking differences existed. The white cells of the pig contained tryptic ferments, those of the dog contained none. Serum of the guineapig was rich in proteolytic ferment; serum of the dog contained little, if any. Furthermore, it seemed likely that the liver was essential to anaphylactic shock in the dog, whereas it played no role in the guineapig. Possibly, therefore, the mechanism in the two species was entirely different, as was further indicated by the rather striking differences in the anaphylactic symptoms themselves. They knew with certainty that serum changes of chemical nature accompanied anaphylactic shock in the dog. This fact, however, by no means argued that these changes were productive of the anaphylactic symptoms. Those symptoms might result from the gradual development of the cellular response to the antigen, taking place, however, more slowly and more gradually than in the guineapig, just exactly as diphtheria toxin produced its effect slowly and gradually. In other words, as he had already stated, it still remained to determine whether serum changes in the dog, resulting in the production of some unidentified substance described as

anaphylatoxin, were simply an accompaniment of anaphylactic shock in that animal, or were actually productive of the symptoms thereof.

Allergic Skin Reactions as an Index of Immunity.—Dr. JOHN A. KOLMER, of Philadelphia, explained that his experiments were undertaken primarily to determine if the serums of persons and animals reacting positively and negatively to various allergic skin tests contained lytic antibodies for the corresponding living microorganisms, and if so, whether or not these antibodies bore a quantitative relationship to the allergic reactions; secondarily, to determine the relationship, if any, among bacteriolytic, agglutinating, and complement-fixing antibodies in the serums of persons and animals reacting variously to allergic skin tests. The serums of persons reacting positively and negatively to the typhoidin, luetin, and diphtherin tests were studied; also the serums of dogs reacting positively and negatively to the intracutaneous injection of an emulsion of Bacillus bronchisepticus.

Bactericidal tests with Bacillus typhosus, Bacillus diphtheriæ, and Bacillus bronchisepticus were conducted with a modified looped pipette method of Wright; spirocheticidal tests *in vitro* were conducted with a pure culture of Treponema pallidum. The serums of normal persons possessed a marked bactericidal power for Bacillus typhosus; the bacteriolysis for Bacillus typhosus in the serums of normal persons and persons who had typhoid fever or had been immunized with typhoid vaccine, was high, but bore no relation to the typhoidin skin reactions.

The serums of syphilitic persons in the tertiary stages who reacted positively and negatively to the luetin skin test and the serums of normal persons showed no appreciable spirochetical activity for a pure culture of Treponema pallidum. The serums of persons reacting positively and negatively to the intracutaneous injection of a washed polyvalent antigen of diphtheria bacilli showed an absence of bactericidal power for Bacillus diphtheriæ. The serums of dogs suffering with distemper; also the serums of healthy dogs and dogs immunized with Bacillus bronchisepticus and reacting positively and negatively to an intracutaneous allergic reaction, were found to be without appreciable bactericidal power for Bacillus bronchisepticus.

Agglutinins and complement-fixing antibodies in the serums of persons and animals for these various microorganisms bore no relation to the skin reactions. These studies demonstrated that there was no experimental support for the theory that allergic skin reactions might be taken as an index to resistance and immunity in so far as it was possible to determine the presence of antibodies *in vitro*.

Immunity Results Obtained from Diphtheria Toxin—Antitoxin Mixtures and the Schick Test.—Dr. WILLIAM H. PARK and Dr. A. ZINGHER, of New York, presented a series of over one thousand cases that had been actively immunized with diphtheria toxin-antitoxin. These susceptible individuals were selected by means of the Schick test out of a total of about 10,000 children and adults in ten different institutions. The mixtures of toxin-antitoxin used for immunization were either neutral (sixty-six to seventy per cent. L+ to each unit of antitoxin) or slightly toxic (eighty to ninety per cent. L+ to each unit of antitoxin) to the guineapig. The dose was varied from 0.5 c. c. to one c. c., and the number of injections from one to three. The injections were made subcutaneously at intervals of seven days. The local reactions at the site of injection were generally mild; in the older children and adults, the redness and swelling were more marked. General symptoms, like malaise, and a temperature of 100 to 102° F. were noted in ten to twenty per cent. of the cases; in a few the temperature reached 104° F. The symptoms lasted from twenty-four to forty-eight hours, and then rapidly subsided. Both local and general symptoms were especially evident in those who showed a susceptibility to the protein by giving a combined false and true Schick reaction. No harmful aftereffects were noted in several thousand injections.

The retests with the Schick reaction showed that only thirty to forty per cent. became immune three weeks after the first injection; about fifty per cent. at four weeks, seventy to eighty per cent. at six weeks, and ninety to ninety-five per cent. at eight to twelve weeks. The best results were obtained with the full immunization, consisting of three injections of one c. c. each, given at weekly intervals. The duration of the active immunity was studied in a group of children that were followed up for over one year and six months; these cases showed that the active immunity persisted for at least that length of time. It was possible that the immunity induced by the injections of toxin-antitoxin started a continued cellular production of antitoxin, which would have otherwise appeared much later in life.

From their results Park and Zingher concluded that it was advisable to immunize children soon after the first year of life, so as to afford them a protection against diphtheria at a time when the disease was most dangerous. In addition, such young children, by not having any hypersensitiveness to the bacillus protein, showed very mild local and constitutional symptoms after the injections. An immune child population could thus be developed, with the result that fresh clinical cases would be prevented and the bacillus carrier would probably soon disappear as a hygienic factor in their communities.

Interesting and parallel results were noted in guineapigs and horses. Guineapigs were fairly resistant to active immunization with diphtheria toxin-antitoxin, and in that respect showed an almost complete parallelism to the positive Schick cases among human beings. After injection of toxin-antitoxin, an antitoxic immunity developed slowly from the sixth to the eighth week. Horses, on the other hand, as a rule corresponded in their behavior toward small doses of toxin-antitoxin to human beings, who were naturally immune. Both gave a ready response, even after a single injection of toxin-antitoxin, and showed a distinct increase in the antitoxin content toward the end of the first week. Occasionally, a horse was found that had no antitoxin in the control bleeding; such animals responded slowly to small doses of toxin-antitoxin. It was probable that the tissue cells of the naturally immune human beings and the majority of horses

had acquired the property of giving a quick and easy response to the stimulation of diphtheria toxin.

The use of the Schick test in the selection of susceptible children for immunization and in controlling the results of the treatment was justified by the great clinical accuracy which the test had shown during a period of several years in the separation of the susceptible from the immune individuals. The test should be carried out properly with a fresh toxin solution, and the results read daily, for a period of seventy-two to ninety-six hours. The pseudoreactions should be controlled with heated toxin, or recognized by their rapid disappearance after seventy-two hours. It was only these individuals who gave the more marked local reactions after the injections of toxin-antitoxin.

In conclusion, Doctor Park and Doctor Zingher stated that the research laboratory of the New York health department would supply those who were connected with institutions and interested in the work, both the toxin for the Schick test and the toxin-antitoxin for immunization.

Anaphylactic Food Reactions in Skin Diseases, with Special Reference to Eczema.—This paper, by Dr. Albert Strickler, of Philadelphia, appeared in the Journal for July 29, 1916, page 198.

Localization of a Streptococcus in Animals from a Case of Recurring Neuritis and Myositis.—Dr. Edward C. Rosenow, of Rochester, Minn., announced that a streptococcus having peculiar properties was isolated from the dead pulp of the left upper first molar in the region where the attacks of pain usually began. The streptococcus was also demonstrated in the sections and isolated from the infiltrated deep fascia and muscles of the left side of the neck. A similar streptococcus was isolated from the pharynx and stool. This streptococcus was found to have elective affinity for the pulp of teeth, dental nerves, and muscles of animals. It was repeatedly isolated from and demonstrated in the experimental lesions in animals whose blood was sterile; the lesions were again produced on reinjection and the streptococcus again isolated. Many animals appeared to be in pain and one rabbit had marked pain and tenderness over the left upper jaw. This affinity was proved to be absent in the diphtheroid germs and Bacillus fusiformis also isolated from the pulp of the tooth, and in the streptococcus broth culture filtrate. Streptococci from other sources rarely caused lesions in the pulp of teeth and dental nerves. Following the attack, the phagocytic power of the patient's blood over the strain from the tooth was twice that of comparable normal blood. These results would appear to warrant them in drawing the conclusion that the attacks of pain in the face in this patient were due to a streptococcus infection of the sheaths of the dental nerves, and that the pain, swelling, and tenderness and spasm of the muscles of the neck were due to fibrositis, the result of infection by this streptococcus. The demonstration of living streptococci in the pulp of the tooth and in the fascia and muscle during quiescent periods was significant and might explain the recurrence of the attacks.

Book Reviews

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

The Treatment of Diabetes Mellitus. With Observations upon the Disease Based upon One Thousand Cases. By Elliott P. Joslin, M. D., Assistant Professor of Medicine, Harvard Medical School; Consulting Physician, Boston City Hospital, etc. Illustrated. Philadelphia and New York: Lea & Febiger, 1916. Pp. 440. (Price, $4.50.)

Recent years have brought great advances in the knowledge of both the pathogenesis and the treatment of diabetes, but successful care of the diabetic still requires a large measure of that skill which is acquired only through experience. The ideal for a volume on the treatment of diabetes would seem to demand a presentation of a blend of the best of scientific knowledge with wide practical experience. In this new volume Joslin has approached so close to the ideal that it would be extremely difficult to discover wherein he has failed of its attainment. He examines lucidly the older and the newer views as they bear upon the question of treatment and justly weighs the value of each plan advocated. He is an enthusiast in favor of Allen's fasting treatment and justifies his enthusiasm by his own strikingly favorable results. This plan of treatment, like other successful measures, is described clearly and in detail. So nicely balanced has been the author's judgment in the preparation of this volume, that we cannot find one portion which deserves emphasis more than another unless it be to speak with special praise of the section on treatment proper and the section which follows it, setting forth certain aids in practical management. If we were seeking the greatest amount of practical information bearing on the care of diabetics in a readily available form, we could not do better than to turn to Joslin's volume. We have no fear of contradiction when we say that it is one of the best written, sanest, and most practical books on diabetes which has yet been published and that it will prove equally valuable to the scientist studying the disease and to the practitioner trying to help his patients.

Bacteriology, General, Pathological, and Intestinal. By Arthur Isaac Kendall, B. S., Ph.D., Dr. P.H., Professor of Bacteriology in the Northwestern University Medical School, Chicago, Ill. Illustrated with 98 Engravings and 9 Plates. Philadelphia and New York: Lea & Febiger, 1916. Pp. x-651. ($4.50.)

The trend of modern medical science is more and more away from the morphological aspects of life and strongly toward the chemical phenomena. Nowhere is this trend better seen than in the study of nutrition and in the newer field of immunology, but modern bacteriology has not failed to be influenced by this newer point of view. It is from this side that Kendall has written, and his book marks a new departure in textbooks on bacteriology. He has given all that is new in the realm of bacteriological morphology, in the cultivation and identification of bacteria, and in the field covered by bacteriology as we used to know it, but more than this he has chosen to present the matter from its chemical side. Thus he gives the most recent knowledge regarding bacterial metabolism, not only from the standpoint of the bacteria, but also from the more important side of the effects of bacterial metabolism upon the human host. It is his chapters on the physiology, the chemistry, and the metabolism of bacteria, together with those on saprophytism, parasitism, and pathogenism, on infection and immunity, and on anaphylaxis which throw the study of bacteriology into a new and clearer light and which make the book something entirely new in its field. These chapters, together with that on the bacteriology of the digestive tract, lift the volume from the narrow realm of purely technical works and truly force it upon the attention of all progressive clinicians who would gain a clearer insight into the phenomena of diseases of bacterial origin. We should be remiss if we failed, in closing, to compliment the author on the clarity of his style and the interest with which he has invested what has usually been regarded as a dry subject.

Milk and Its Hygienic Relations. By JANET E. LANE-CLAYPON, M. D., D. Sc. (Lond.), Assistant Medical Inspector under the Local Government Board. Published under the Direction of the Medical Research Committee (National Health Insurance). With Eight Plates and Diagrams in the Text. London, Bombay, Calcutta, and Madras: Longmans, Green & Co., 1916. Pp. viii-348. (Price, $2.50.)

In this volume will be found practically all that is of scientific or hygienic interest on the subject of milk. There are chapters on the general composition of milk; the organic and inorganic constituents of milk; the so called biological properties of milk; the cellular content of milk; breast feeding; the nutritive value of raw and of boiled milk; dried milk as a food for infants; the alleged production of Barlow's disease and rickets by the use of heated milk; changes occurring in milk as a result of the application of heat; the presence in milk of certain organisms likely to cause disease; the sources of contamination of milk; the production of milk, as far as possible free from contamination; bacteria commonly found in milk, and their thermal death points; the methods commonly used in the heating of milk; and the presence of pathogenic bacteria in milk and cheese. Each chapter is preceded by a summary of its contents, and is followed by a carefully selected list of references to the literature of the subject; and all of the papers referred to (with the exception of one or two, which were inaccessible) have been read by the author. The book is one of unusual merit, and should appeal to a wide circle of readers. It contains, in readily available form, information that is usually only to be found after a prolonged search in various works on bacteriology, chemistry, physiology, hygiene, dietetics, pediatrics, agricultural science, and innumerable technical journals.

Interclinical Notes

According to *Commerce and Finance* for September 6th, American contributions to the various funds intended for the relief of war sufferers in Europe aggregate $35,000,000, or thirty-five cents per capita. At a low estimate we shall spend $250,000,000, or $2.50 per capita, for jewelry this year. The comparison is not one to be proud of, is it?

* * *

In the *New York American* for September 10, 1916, Dr. Arthur C. Jacobson discussed the physical causes of the death of Christ, coming to the conclusion that the heart ruptured into the pericardium. The thesis is well reasoned out. The premises are far removed, however, from those of Huxley and other scientific writers who have treated of the same death. In George Moore's latest book, *The Brook Kerith,* Christ is supposed to have been rescued from the cross by Joseph of Arimathea before life was extinct, and his faculties having been restored in the cool and quiet tomb, to have spent the rest of his days in a sort of phalanstery, tending the sheep of the brethren. This was also Huxley's theory of the resurrection, although that writer did not speculate on the occurrences of the subsequent forty days.

* * *

The August number of the *Modern Hospital* is devoted to welfare work among the industrial corporations of the country. There are editorial articles by those competent to write on this important subject, a great number of papers written by welfare directors in some of the most important industrial corporations, and an immense amount of statistics and figures and facts showing the huge volume of work that the corporations are doing to protect their employees against sickness, accidents, and discontent. The journal contains many illustrations of first aid stations, emergency hospitals, and welfare departments of industrial plants, and many facts that should be of great help to those interested. Among the topics discussed are those of first aid, industrial nursing, lunches and diets for industrial employees, safety devices in factories, and athletic and social clubs for employees. The editors frankly state that they have been unable to obtain figures as to cost of welfare work in the industries, but a number of writers attempt to make deductions and draw conclusions from their experiences of the past few years.

Meetings of Local Medical Societies

MONDAY, *October 2nd.*—Clinical Society of New York Throat, Nose, and Lung Hospital; German Medical Society of the City of New York; Utica Medical Library Association (annual); Niagara Falls Academy of Medicine; Brooklyn Hospital Club; Hornell Medical and Surgical Association; Clinical Society of the New York Polyclinic Medical School and Hospital; West Side Physicians' Economic League.

TUESDAY, *October 3rd.*—New York Academy of Medicine (Section in Dermatology); New York Neurological Society; Amsterdam City Medical Society; Lockport Academy of Medicine; Society of Alumni of Lebanon Hospital, New York; Syracuse Academy of Medicine; Buffalo Academy of Medicine; Ogdensburg Medical Association; Oswego Academy of Medicine; Medical Association of Troy and Vicinity; Medical Society of the County of Yates; Medical Society of the County of Ulster; Medical Society of the County of Orleans (annual); Medical Society of the County of Cattaraugus.

WEDNESDAY, *October 4th.*—New York Urological Society; Brooklyn Society for Neurology; Society of Alumni of Bellevue Hospital; Harlem Medical Association; Bronx Medical Association; Elmira Academy of Medicine; Schenectady Academy of Medicine.

THURSDAY, *October 5th.*—New York Academy of Medicine (stated meeting); Brooklyn Surgical Society; Practitioners' Club, Buffalo; Geneva Medical Society; Glens Falls Medical and Surgical Society.

Friday, October 6th.—New York Academy of Medicine (Section in Surgery); New Utrecht Medical Society; New York Microscopical Society; Manhattan Dermatological Society; Practitioners' Society of New York; Corning Medical Association; Saratoga Springs Medical Society; Society for Serology and Hematology, New York.

SATURDAY, *October 7th.*—Benjamin Rush Medical Society, New York.

Official News

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers of the United States Public Health Service for the seven days ending September 20, 1916:

ANDERSON, T. B. H., Assistant Surgeon. Bureau letter dated September 7, 1916, amended to grant six days' leave of absence from September 7, 1916.

DERIVAUX, R. C., Assistant Surgeon. Ordered to take temporary charge of Marine Hospital at New Orleans, La., and direct work of malaria investigations.

ESKEY, C. R., Assistant Surgeon. Continued on duty at Chicago, Ill.

FOSTER, M. H., Surgeon. Authorized to travel to different points in Pennsylvania and adjacent States to make investigations relative to prevalence of poliomyelitis and direct officers under him to perform the same duty when necessary.

FROST, W. H., Passed Assistant Surgeon. Relieved from duty at New York, N. Y., and directed to rejoin station at Cincinnati, Ohio, stopping en route at Bureau.

IRWIN, FAIRFAX, Senior Surgeon. Ordered to represent the Service at the meeting of the American Hospital Association, Philadelphia, Pa., September 26-29, 1916.

MCCOY, G. W., Surgeon. Granted seven days' leave of absence en route under Bureau orders of August 29, 1916.

RUCKER, W. C., Assistant Surgeon General. Granted seven days' leave of absence from September 14, 1916.

STOUT, JOSEPH D., Assistant Surgeon. Continued on duty at Stapleton, N. Y.

TREADWAY, W. L., Assistant Surgeon. Relieved from duty at Little Rock, Ark., and directed to report at Washington for duty in field investigations of school hygiene.

Waller, C. E., Assistant Surgeon. Directed to proceed to Philadelphia, Pa., for duty on steamer *Murray*, in investigations of pollution of tidal waters.

Waring, C. H., Assistant Surgeon. Relieved from duty at Jackson, Miss., and directed to proceed to Baltimore, Md., for duty in preventing the spread of poliomyelitis.

Watkins, J. A., Passed Assistant Surgeon. Relieved from duty at New York, N. Y., and directed to rejoin station at Pittsburgh, Pa.

White, J. H., Senior Surgeon. Granted six days' leave of absence from September 17, 1916, under paragraph 193, Service Regulations.

Woods, Edwin O., Assistant Surgeon. Continued on duty at Seattle, Wash.

Young, G. B., Surgeon. Granted two days' additional leave of absence, September 8 and 9, 1916.

United States Navy Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Navy for the two weeks ending September 23, 1916:

Allen, D. G., Passed Assistant Surgeon. Ordered to the *Chester* for duty.

Biello, J. A., Passed Assistant Surgeon. Detached from the New York Recruiting Station and ordered to duty at the Naval Hospital, Portsmouth, N. H.

Blackwood, N. J., Medical Inspector. Detached from the Navy Yard, Boston, Mass., and ordered to command the *Solace*.

Borden, J. T., Assistant Surgeon. Detached from the Marine Brigade, Port-au-Prince, Haiti, and ordered to duty as inspector in the Haitian Constabulary.

Buckley, John, Passed Assistant Surgeon. Commissioned a passed assistant surgeon from February 4, 1916.

Carson, V. H., Assistant Surgeon. Detached from the Marine Expeditionary Force, San Domingo, and ordered to duty on the *Castine*.

Curl, H. C., Surgeon. Detached from duty as force surgeon, Atlantic Fleet, and ordered to duty at the Marine Barracks, Port Royal, S. C.

Drum, W. M., Assistant Surgeon, Medical Reserve Corps. Appointed an assistant surgeon from August 25, 1916.

Dunn, W. M., Acting Assistant Surgeon. Ordered to duty at the Marine Recruiting Station, Atlanta, Ga.

Francis, C. H., Assistant Surgeon. Commissioned as assistant surgeon from August 10, 1916.

Freeman, G. F., Surgeon. Detached from the *Tacoma* and ordered home to await orders.

Garrison, P. E., Passed Assistant Surgeon. Detached from the *Dolphin* and ordered to duty with Expeditionary Force, San Domingo.

Gatewood, J. D., Medical Director. Detached from command at Naval Medical School, Washington, D. C., and ordered to duty at Bureau of Medicine and Surgery, Navy Department.

Gibson, Gordon, Assistant Surgeon. Commissioned an assistant surgeon from August 10, 1916.

Helm, J. B., Assistant Surgeon. Detached from the *Castine* and ordered to duty as inspector in the Haitian Constabulary.

Kennedy, R. M., Medical Inspector. Detached from the *Solace* and ordered home to await orders; ordered to command Naval Hospital, Washington, D. C.

Koltes, F. X., Surgeon. Detached from the First Brigade of Marines, Port-au-Prince, Haiti, and ordered to duty as director of Haitian Constabulary.

Leys, J. F., Surgeon. Ordered to duty at Navy Yard, Boston, Mass.

May, H. A., Passed Assistant Surgeon. Detached from the Marine Barracks, Port Royal, S. C., and ordered home to await orders.

Ohnesorg, Karl, Surgeon. Detached from duty as assistant naval attaché, Berlin, Germany, and given leave of absence.

Old, E. H. H., Passed Assistant Surgeon. Detached from duty at the Naval Medical School and at the Naval Hospital, Washington, D. C., and ordered to duty on the *Solace*.

Plummer, R. W., Surgeon. Ordered to duty on the *Alabama*.

Pryor, J. C., Surgeon. Detached from the Bureau of Medicine and Surgery, Washington, D. C., and ordered to duty at the Naval Medical School.

Rushmore, J. C., Assistant Surgeon. Commissioned an assistant surgeon from August 10, 1916.

Shepard, G. W., Passed Assistant Surgeon. Ordered to duty on Receiving Ship, Norfolk, Va., September 25, 1916.

Stitt, E. R., Medical Director. Ordered to command Naval Medical School, Washington, D. C., September 25, 1916.

Strine, H. F., Surgeon. Ordered to duty at Naval Hospital and Medical School, Washington, D. C., September 25, 1916.

Stuart, M. A., Passed Assistant Surgeon. Ordered to duty at the Navy Yard, Norfolk, Va.

Sutton, D. G., Passed Assistant Surgeon. Detached from the *Chester* and ordered to duty at the Naval Medical School, Washington, D. C.

Taylor, J. S., Surgeon. Detached from the *Alabama* and ordered to duty as force surgeon, Reserve Force, Atlantic Fleet, on the *Rhode Island*.

Trible, G. B., Passed Assistant Surgeon. Ordered to duty at Naval Academy, Annapolis, Md., September 25, 1916.

The following named assistant surgeons of the Medical Reserve Corps have been ordered to the Naval Medical School, Washington, D. C., September 25, 1916, for a course of instruction: L. H. Williams, F. F. Murdock, O. D. King, A. C. Sinton, C. H. Francis, J. J. Laughlin, J. A. Halpin, T. E. Cox, A. W. Hoagland, A. M. Larson, F. T. Bower, I. W. Jacobs, A. H. Gecha, P. F. Prioleau, J. C. Brentley.

Births, Marriages, and Deaths

Married.

Boyle-Donaghue.—In Hartford, Conn., on Thursday, September 14th, Dr. Robert J. Boyle and Miss Sarah Donaghue.

Griffin-O'Brennan.—In Bridgeport, Conn., on Thursday, September 14th, Dr. Daniel P. Griffin and Miss Mabel O'Brennan.

Died.

Brown.—In Monticello, Ark., on Wednesday, September 6th, Dr. William A. Brown, aged seventy-four years.

Crump.—In West Point, Miss., on Tuesday, September 5th, Dr. L. L. Crump.

Davis.—In Cincinnati, Ohio, on Friday, September 8th, Dr. Walter L. Davis, aged seventy-two years.

Estes.—In Georgetown, Ky., on Tuesday, September 12th, Dr. John W. Estes, aged seventy-six years.

Hogan.—In Brooklyn, N. Y., on Sunday, September 17th, Dr. Patrick F. Hogan, aged sixty-four years.

Judson.—In New York, on Wednesday, September 20th, Dr. Adoniram Brown Judson, aged eighty years.

King.—In Atlanta, Ga., on Friday, September 8th, Dr. Aaron J. King, aged sixty-eight years.

Keenan.—In Elizabeth, N. J., on Monday, September 18th, Dr. J. Herbert Keenan.

Mackay.—In Peacham, Vermont, on Monday, September 11th, Dr. Albert J. Mackay, aged fifty years.

Mayfield.—In St. Louis, Mo., on Tuesday, September 12th, Dr. William Henderson Mayfield, aged sixty-four years.

Moore.—In Rochester, N. Y., on Wednesday, September 13th, Dr. Richard M. Moore, aged sixty-one years.

Pickard.—In Mikana, Wis., on Sunday, September 10th, Dr. William S. Pickard, of Maywood, Ill., aged fifty-seven years.

Reid.—In Baltimore Md., on Tuesday, September 12th, Dr. E. Miller Reid, aged seventy-two years.

Shannon.—In Saco, Me., on Thursday, September 14th, Dr. James H. Shannon, aged seventy-five years.

Shoemaker.—In Des Moines, Iowa, on Monday, September 11th, Dr. Oliver H. P. Shoemaker, aged sixty-eight years.

Sumner.—In Maysfield Center, Conn., on Wednesday, September 13th, Dr. Edwin G. Sumner, aged eighty-six years.

Van Valzah.—In Springfield, Ore., on Tuesday, September 5th, Dr. Robert G. Van Valzah.

Whiting.—In Baltimore, Md., on Monday, September 11th, Dr. Charles H. Whiting.

THE THERAPEUTICS OF HAY FEVER.*

An Historical Review,

BY A. PARKER HITCHENS, M. D.,

Glenolden, Pa.

It is hardly possible to arrange a strictly chronological review of all the types of treatment which have been used in hay fever. For although the early period may be said to have been characterized by the purely empirical use of various remedies, both general and local, the later efforts to establish the therapeutics upon a more definite etiology did not result in the rejection of the older methods of treatment. Even in the light of the recent advances in etiology and specific therapeutics, many physicians are still reluctant to discard the most irrelevant remedies, and frequently combine all classes of treatment. The following outline, therefore, is merely an attempt to classify roughly the principal types of treatment without strict regard to chronology.

I. SYSTEMIC TREATMENT.

The earlier writers, lacking a definite hypothesis for the cause of hay fever, resorted to constitutional treatment on general principles. Such hygienic measures as regulated diet, purgatives, plenty of sleep, more or less exercise, baths, etc., were advised by Bostock (1), Gordon (2), Elliottson (3), Cazenave (4), King (5), Phœbus (6), Melville (7), Blackley (8), etc. In addition, certain internal remedies were advised by these authors, all with the purpose of toning up the system. Quinine, iron, strychnine, arsenic, etc., were the drugs most commonly used, and these are still included in the "tonic treatment" so often prescribed at the present day.

During the later decades of the eighteenth century, hypotheses regarding etiology based generally upon current medical thought, began to assume definite shape. Accordingly, systemic treatment, advised in hay fever, was aimed against certain supposed defective elements in the individual constitution.

Nervous diathesis. The nervous diathesis was first suggested by Pirrie (9), in 1867; Beard (10), and Morell Mackenzie (11) were probably the most notable exponents of this theory. To raise the tone of the nervous system was, of course, their chief aim in treatment. Beard lists a large number of remedies "on the basis of what they have accomplished in other affections," and recommends that patients permit themselves to be experimented upon, since "in the light of the suggestions given below, they will, in nearly every case, find something that will give them sufficient relief to more than compensate for all their efforts." Beard's list includes quinine, arsenic, whiskey, galvanic electricity applied centrally and locally, strychnine and iron, phosphorus and codliver oil, Turkish and Russian baths, opiates, cold powder (camphor, ammonium carbonate, and powdered opium) locally, potassium bromide and chloral hydrate, belladonna, iodine, potassium iodide, aconite, digitalis, veratrum viride, gelsemium, guarana, caffeine, ammonium chloride, hydrocyanic acid, amyl nitrite, iodoform ("works admirably as a tonic and in hysteria and allied disorders"), ergot, ipecac, inhalations of ether or chloroform for temporary relief, Apocynum andromifolium, Grindelia robusta.

Arthritic theory. The so called "arthritic" theory, inaugurated by De Mussy (12), in 1868, seems to be essentially French, supported as it was by Herbert (13), Giffo (14), Mollière (15), Leflaive (16), Joal (17), etc.

Uric acid theory. A similar view, however—the "uric acid" theory—has been advocated in England and America. Bishop (18), Tyrrell (19), Floyd (20), Dickie (21), Woodring (22), Gleason (23), Grube (24), Parsons (25), Tobias (26), and others in accord with this view have treated hay fever much as they treated "lithemia"—lithium salts, salicylates, hydrotherapy being the principal measures prescribed.

In addition to the above mentioned attempts to "fortify the system" against hay fever, certain other internal remedies have been administered with the purpose of influencing more or less directly the local symptoms.

Nux vomica (Gream, 27), valerian with senna (Prater, 28), opium and belladonna (Lennox Browne, 30), morphine (hypodermically, Moss, 31), (Moorhead, 32), morphine and atropine (Bishop, 18), (Thornton, 33), thyroidine (Heymann, 34), hydrastis (Imhofer, 35), ergotin and hydrastis (Hoffmann, 36), muriatic acid (Strangways, 37)[1], dionin and atropine (Goetz, 38), suprarenal ex-

*Read before the American Therapeutic Society, Detroit, June 10, 1916.

[1]In conjunction with the acid treatment, this author prescribes an acid douche for the nose.

tract (Solis-Cohen, 39), (Parsons, 25), (Douglass, 40), terpin hydrate (for asthmatic symptoms, Loebinger, 41), (Rixa, 42b).

Calcium treatment. Calcium salts (Emmerich and Loew, 43), (Wilson, 44), etc., have received some attention in recent literature, but have not been used very extensively. The benefit, if indeed there is any, is believed by some writers to depend upon a physicochemical change in the body fluids. Wright (45) explains the action in reducing a tendency to urticaria upon the basis of increased coagulability of the blood. Clowes (46b) states that "a nonspecific immunization or rather reduction in sensitiveness, may be effected in certain cases by administering large doses of calcium lactate. It is worthy of note that well nourished individuals appear to respond most readily to treatment with calcium salts."

It is possible that calcium salts may exert the action attributed to their use, but if so, the proper mode of administration has not yet been ascertained in order to make it a trustworthy remedy in hay fever.

II. LOCAL TREATMENT.

From the time of Bostock (1), local palliatives of every variety have been used, usually in combination with other measures.

1. *Medicinal applications:* Inhalations. Chlorinated lime solution (Elliottson, 3), camphor solution (Bradbury, 47), (Parsons, 25), ammoniated steam (Chambers, 48), salicylic acid (W. J. H. Wood, 49), ethyl iodide (Capp, 50), menthol (Immerwahr, 51), (Ruault, 52), (MacBride, 53), chloroform (Thornton, 33), cigarettes (Simes Thompson, 54), (Marsh, 55), (Windle, 56).

Sprays and nasal douches, on the whole, have been more popular than inhalations. Indeed, so many kinds of sprays—alkaline, acid, mentholated oil, etc.—have been mentioned in the literature, that no attempt can be made to enumerate them here; each physician seems to have advised an individual modification. Dobell's solution has probably been as widely used as any.

Salves and ointments are frequently applied after the spray. The proprietary rhinoculin cream and bormelin have a considerable vogue in Germany. In this country an ointment containing epinephrine is popular.

Insufflations, such as aristol and thymol iodide, have been used by Fink (57) and Schädle (58) respectively.

Cocaine was introduced into hay fever therapeutics about 1885, and on account of the immediate relief following its application it has been more widely experimented with perhaps than any other single palliative. Bosworth (59) asserts that he was the first to use this remedy for asthmatic attacks. It was further recommended by Bishop (18), Watson (60), Schädle (58), Logan (61), Capp (50), Leflaive (16), Douglass (40), Perkins (62), etc. More recent authors, however, warn against cocaine on account of its habit forming tendencies; moreover, it is said gradually to lose its effect with continued use. Cocaine combined with epinephrine, has been used by Van Eden (63), Hobbs (64), Rabé (65), etc. Other palliatives are: Anesthesin (Kuhnt, 66), orthoform (Lichtwitz, 67), (E. W. Wright, 68), menthospirin (Hirschberg, 69).

Suprarenal extract has been used locally by Somers (70a), Sajous (71), J. Payson Clark (72), Persons (73), Jervey (74), Parsons (25), E. W. Wright (68), and others. The suprarenal gland and its active principle, epinephrine, are undoubtedly the safest drugs we have for the immediate relief of symptoms; the chief drawback is the evanescent nature of the relief. Some patients are said to be hypersensitive to the desiccated gland.

2. *Surgical treatment.* The discovery in 1881 of "hyperesthetic" nasal areas by Daly marked a distinct epoch in the treatment of hay fever. The "nasal theory" still has many firm adherents at the present day.

The principal methods of dealing with the sensitive areas in the nose are indicated below, but let it be understood that hardly any physician has used *only* that method under which his name appears—it merely represents in general the method of treatment he apparently preferred.

Removal of abnormalities, before further procedure, has been recommended by practically all the authors cited below. Often such operations as partial turbinectomy (Bardes, 76), (Moulton, 77), (Berbineau, 78) have been considered sufficient.

The galvanocautery has been used (Daly, 75), (Roe, 79), (H. Allen, 80), (J. N. Mackenzie, 8), (Beverly Robinson, 82), (Sajous, 71), (Rumbold, 83), (R. Thomas, 84), (Klingensmith, 85), (Rixa, 42), (Taylor, 86), etc., in America; and in Europe (Hack, 87), (Beschorner, 88), (Ruault, 52), (Moure, 89), (Natier, 90), (Joal, 17), (Baratoux, 91), (Lennox Browne, 30), (Hall, 92), (Williams, 93), very light cauterization (Bonnier, 94).

Chemical cauterization, chiefly with nitric, chromic, and glacial acetic acids has had advocates (Cazenave, 4), (Logan, 61), (Browne, 30), (Taylor, 86), nitric (Crippen, 95), (A. Clark, 96), carbolic acid mixture (Douglass, 40), (Parsons, 25), (Cheatham, 29).

Intraneural injections of alcohol have been recently introduced by Stein (97b).

Resection of the ethmoid was first practised by Yonge (98), in 1907, but no permanent results were reported. Blos (99), in Germany, tried this operation in three cases. Albrecht (100a) considered the method quite unjustifiable.

Massage of the nasal mucous membrane has been tried (Urbantschitsch, 101), (Denker, 102), (E. W. Wright, 68), etc. A "scrubbing" process was used by Hollopeter (103).

Hot air has been applied to the mucous membranes by Lermoyez and Mahu (104).

3. *Mechanical contrivances* for keeping the external irritants from contact with the eyes and nose are still in common use as accessory treatment.

Smoked glasses (light was considered one of the external irritants) have been prescribed (Stowell, 105; Leflaive, 16; Hobbs, 64; Townsend, 106; Rabé 65; Luda, 107, etc.); also nasal filters or plugs by Blackley (8), Thorowgood (108), Mohr (109), Van Eden (63), Thost (110a), Luda (107), Imhofer (35), Rabé (65), O'Connell (111), Hobbs (64), Townsend (106), Ebstein (112), Hoffmann (36);

lady's veil (Sebastian) (113); and a spring clip for the nose and glass tubes for the lacrymal ducts (Hannay, 114).

III. CLIMATIC TREATMENT.

A change of residence during the hay fever season is obviously impracticable for the majority of patients. But, granted the opportunity, it is not always easy to find a region absolutely satisfactory for every patient. In Europe even the much famed Heligoland has proved a disappointment to many patients (Liebermann, 115), (Bachem, 116).

In America, the White Mountains were made popular by Morrill Wyman (117) and Beard (10). More recently, however, many other resorts have been recommended.[2]

Alton (118) described the ideal spot as a camp in a virgin forest on the rocky shores of a mountain lake, etc. But characteristically enough, in the discussion which followed the reading of his paper, scarcely any one agreed with the author. Each patient must learn by experience what type of resort is most suitable for his requirements; and however desirable the location may be, it must not be forgotten that paroxysms are still possible from the unpacking of clothing, high winds, etc.

An ocean voyage seems to be the ideal means for escaping vegetation, but here again there is a chance of failure; for instance, a susceptible person should avoid traveling on a cattle boat.

Where change of residence is impossible, an injunction often given is to remain in a closed room or to avoid the country. A curious "cold storage" treatment was described in 1911 by Porteous (119), who believes that "the climatic relief usually experienced is not to be credited to any pollen-free or bacteria-free atmosphere, but to the general diminution of atmospheric temperature which it provides for an overworked vasodilator mechanism in the upper respiratory field." The author accordingly suggests the possibility of providing refrigeratoriums for hay fever patients.

Another measure which might be considered under climatic treatment is the destruction of ragweed recently advocated enthusiastically by Scheppegrell (120b), of New Orleans.

The three factor theory. By the end of the eighties, all the possible hypotheses regarding a single cause of hay fever had received a hearing. From the standpoint of therapeutics, however, these theories had been far from satisfactory. Many writers had held certain constitutional defects accountable for the disease, but as yet no plan of systemic treatment had succeeded in relieving the symptoms. Blackley (8) had conclusively demonstrated the pollen theory, but his admirable researches had nothing to suggest of therapeutic value. Even the nasal theory did not fulfill its promise so far as permanent results were concerned. There was a large number of patients in whom no pathological lesions nor sensitive areas could be found; the prognosis in such cases was admittedly unfavorable.

It was apparently the inadequacy of existing therapeutic methods in hay fever that led to the formulation of what might be called the "three factor etiology." According to this theory, three elements were necessary to produce hay fever:

1. Some constitutional defect.
2. Pathological conditions in the nose.
3. An external irritant.

The absence of one of these factors was considered sufficient to prevent the appearance of symptoms. The way was thus opened for the application of three different types of treatment. If one factor eluded the efforts of the physician, there was still a chance of successfully attacking the second or third links in the chain of causes. The convenience of a theory so comprehensive in scope naturally attracted the support even of those who still remained adherents of one particular type of treatment. The popularity of the three factor theory has continued down to the present day. A few of its exponents have been Sir Andrew Clark (96), Sajous (71), Hurt (121), Kyle (122), Hall (92), Thornton (33), Williams (93), Perkins (123), Gleason (23), Parsons (25), Floyd (20), Muckey (124), Crane (125), Latchford (126), Rabe (65), Murphy (127), etc.

IV. SPECIFIC TREATMENT: PASSIVE IMMUNIZATION.

As to passive immunization, it is to Dunbar (128) that we owe the first confirmation of the work of Blackley (8) concerning the specific cause of hay fever, and credit must also be given Dunbar (128) for being the first to establish a system of treatment based upon immunological methods. He considered that he and his associates succeeded in isolating from pollen a substance which had the properties of a true toxin when applied to susceptible persons. Upon this hypothesis he prepared an antitoxin by the injection of horses and other animals. After careful treatment over a period of some months the blood serum of the animals was found to have acquired the property of neutralizing the effect of pollen and eventually of the so called toxin, when applied to the skin, nasal mucous membrane, or conjunctiva of susceptible persons. After elaborate experimentation, the so called antitoxin, under the name of "pollantin," was placed upon the market and has been in more or less common use for more than a decade.

The results obtained from the use of pollantin may be seen in the following reports:

	Satisfactory.	Partially Satisfactory.	Negative.
	Per cent.	Per cent.	Per cent.
Lübbert (129) (505 cases)	59.2	28.3	12.5
Zarniko (130) (492 cases)	61.3	23.1	15.6

In 1906 Knight (131), published the following figures compiled from the report of eighty-one physicians in the United States:

		Per cent.
Effectively benefited	114	or 52
Partially benefited	66	or 30
Not benefited	39	or 18
	219	100

Sixty-eight of these had asthma.

Of these were		Per cent.
Effectively benefited	30	or 44
Partially benefited	26	or 36
Not benefited	13	or 20

Thost (110), Glegg (154), Wolff (155), Kuttner (156), Somers (70b), Albrecht (100b), Hobbs (64), Stein (97), King (158), Rosenberg (159), Joachim (160), give favorable reports of pollantin

[2] The author, in a cursory botanical survey of the country about Percé, P. Q., on the Gaspé peninsula, made recently, found an entire absence of ragweed and a very small amount of goldenrod. Therefore, persons with the common fall type of hay fever would find complete relief from symptoms in this region.

in the majority of cases, while Mohr (109), Van Eden (63), Leslie (161), MacBride (53), Borrowman (162), Beaudoux (163), Immerwahr (51), report chiefly negative or only partial results.

The limitations of pollantin are those which might be expected from a remedy whose period of activity corresponds only with its presence upon the susceptible areas. The best results, therefore, are obtained when it is used before the attacks begin.

Local conditions in the nose have much to do with the efficacy of a local remedy, and it is easy to conceive of certain pathological conditions in which pollantin might not have a fair chance to demonstrate its effect.

A further disadvantage is that a certain proportion of hay fever patients are susceptible to horse proteins or acquire such hypersusceptibility upon the repeated application of this remedy.

Notwithstanding its limitations, however, pollantin does give definite relief in many cases and will probably continue to be used as a standard remedy by those who have experienced benefit from its application.

ACTIVE IMMUNIZATION.

Curtis (132), in 1900, seems to have made the first attempts to immunize actively against hay fever. He used aqueous and alcoholic extracts of ragweed, goldenrod, lily of the valley, etc. Curtis (132) at first administered his liquor ambrosia hypodermically, but he soon abandoned this method and gave the doses entirely by mouth. In over 100 cases reported, about sixty per cent. were said to be immunized against ragweed. Ingals (133), in applying this same treatment, obtained successful results in sixty-seven per cent. of cases. For some reason this method of immunization does not seem to have been continued.

An interesting but different plan of immunization was suggested, in 1908, by Scheppegrell (120a), who thought that if patients sniffed the dried pollen for from two to six weeks before the season, a permanent tolerance might gradually develop. Although this treatment produced good results in a considerable number of cases, the effects were not prolonged beyond the hay fever season, and the treatment was gradually discontinued.

Dunbar (128) tried active immunization, but discontinued his experiments upon noting the severe reactions after injection. Later, he made some observations upon "neutralized mixtures of toxin and antitoxin." In one patient the result was encouraging. Later, after the publication of Noon's work, he treated ten cases with pollen extract. The results were generally favorable.

It remained for Noon (134) and Freeman (135) to establish active immunization in hay fever upon a practical basis. These investigators controlled their doses and standardized their pollen extracts by noting the amount of extract required to produce inflammation when applied to the conjunctiva of susceptible subjects. In this respect they adopted practically the methods worked out by Dunbar (128). In 1914, Freeman (135) published the following results of treatment in eighty-four cases experiencing an aggregate of 113 seasons:

In thirty-four seasons (30.1 per cent.), the hay fever was completely cured or was so slight as to be insignificant.

In thirty-nine seasons (34.5 per cent.), the hay fever was greatly diminished.

In twenty-seven seasons (23.9 per cent.), the hay fever was admittedly diminished, but only to a slight extent.

In thirteen seasons (11.5 per cent.), the hay fever was no better, and of these, two patients reported that they were worse.

Since the publications of Noon (134) and Freeman (135) other writers have reported their experience with vaccine treatment. Lovell (136), in 1912, described five cases treated with pollen vaccine, three of which were markedly benefited. Two years later he reported eleven cases, three of which showed very satisfactory results, and two fair results. Ellern (137), in 1912, used pollen vaccine upon thirteen patients. Although the majority were considerably improved, he did not consider the results conclusive because the symptoms of many other patients were less severe that season.

The first report in this country was published by Clowes (1912). He used two methods of extraction: 1. That previously used by Dunbar (128), consisting of repeated freezing and thawing in five per cent. aqueous suspension; 2, an original method, which consisted of precipitating pollen with acetone and extracting with water. Doses ranged from one c. c. of one in 5,000,000 to one c. c. of one in 500,000. Doses, intervals, etc., were regulated by frequent ophthalmic, cutaneous, and blood tests. The eight cases treated by Clowes all showed marked alleviation of general symptoms.

Alexander (138), in 1914, reported his results with fifteen cases treated with pollen vaccine. Of these eleven were successfully treated, while four showed uncertain results—these four were treated during the hay fever season.

Lowdermilk (139), in 1914, extracted the protein with physiological saline solution. He first ground the pollen with sterile sand, moistening the pollen from time to time with a portion of the salt solution. After grinding for several hours, the remainder of the salt solution was added, the whole mixture transferred to a sterile flask, and shaken frequently during twenty-four hours. After centrifugation the supernatant fluid was used for treatment. The results were satisfactory in sixteen out of nineteen cases.

Ulrich (140), in 1914, made his extract according to Dunbar's method and administered it in very small doses at intervals of one, two, and three days. He treated twelve cases, the majority of which were relieved in from fifteen minutes to two hours. This relief lasted from a few hours to several days.

Koessler (141), in 1914, made three extracts: 1. Saline extract; 2, alcoholic extract; 3, extract by Vaughan's method. Ragweed pollen was used exclusively. Forty-one cases were treated during four years. Four were completely cured, twenty-nine markedly improved, eight unimproved.

Manning (142) in 1915, made his extracts by grinding the pollen with sterile sand and using 10 x physiological saline solution. The extract was afterward diluted to ten times its bulk with distilled water. Of his twenty-one cases, fourteen were definitely relieved.

Cooke (143a), in 1915, ground the pollen in a mortar with sand, using $\frac{N}{200}$ sodium hydroxide and nine per cent. sodium chloride solution. After shaking for twenty-four hours, the preparation was passed, first through sand, and then through a sterile Berkefeld filter. The determination of protein was made by the Kjeldahl method, $\frac{N}{50}$ solutions being used for the titration. The extract was preserved with 0.5 per cent. carbolic acid. Cooke's method of standardization seems to be the most accurate so far.

Of the early type, Cooke (143a) reports sixty-four cases: 60.5 per cent. with marked improvement, 31 per cent. improved, and 8.5 per cent. unimproved. Of the late type, he treated eighty cases: 25 per cent. with marked improvement, 50 per cent. improved, and 25 per cent. unimproved.

Wood (144), in 1915, suspended the pollen in saline solution, sterilized it by heat at 56° C. and the addition of two per cent. phenol. This solution was diluted with saline so that each c. c. would contain about 0.00002 mg. of pollen. Apparently a separation of the proteins from the other portion of the pollen was not made. Wood treated twenty cases, of which only two were failures.

Goodale (145a), in 1915, considered water sufficient for extraction. He said he prevented deterioration by adding from thirteen to fifteen per cent. alcohol. Of the 123 cases treated, one fourth were undoubtedly benefited. The attempts of Goodale to classify the susceptibility of patients according to natural orders of the plants, and thus to work out this part of the problem systematically, opens up many interesting possibilities, not only in hay fever treatment, but also in botanical classification.

Sormani (146), in 1916, reported the results of vaccine treatment carried out during the season of 1915. He prepared his extract by grinding the pollen with sterile sand and using distilled water for extraction; he sterilized the preparation by adding one tenth of its volume of five per cent. phenol solution, after which salt was added up to 0.85 per cent. Sormani reports the results as follows:

1. Of fourteen patients treated prophylactically, six were competely cured, six greatly benefited, two but little benefited.

2. Of twelve patients treated only prophylactically, four were completely cured, three more or less relieved, five not relieved.

3. Of nineteen patients treated prophylactically by other physicians, all found much relief, while of three treated therapeutically, all found relief.

PREPARATION OF EXTRACT.

It was about four years ago that the author of this paper became interested in the possibilities of vaccine treatment in hay fever. The results of the work in collaboration with C. P. Brown (147) were published a few months ago. The technic of preparing the vaccine was as follows: To obtain the pollen the flowers are gathered just when pollination has started. The flowers are dried and the pollen is collected by fine sieves. The pollen is preserved in the dry state until it is to be extracted.

1. The pollen is mixed with sufficient distilled water to make a fairly thick paste.

2. The paste is transferred to a porcelain ball mill and ground for twenty-four hours, or until microscopic examination shows that the pollen grains are broken.

3. More distilled water is added and the mixture is centrifugated to remove insoluble débris.

4. The extracted protein is purified by precipitation with acetone.

5. The precipitate is dissolved in physiological saline solution. The amount of protein-nitrogen in this solution is determined by the Kjeldahl method.

6. The solution is then diluted so that each c. c. contains certain fractions of one mgm. of protein nitrogen. The lowest dilution (one c. c. of which may be used as the initial dose in treatment) contains 0.0025 mg. protein nitrogen.

7. The final solutions are preserved from contamination by the addition of 0.3 per cent. three cresols and sterilized by filtration. Sterility is determined by careful aerobic and anaerobic cultural tests.

	Hay fever absent or insignificant.	Hay fever greatly diminished.	Hay fever no better or only slightly diminished.	No report.
18 cases with asthma as complicating symptom	11 61.1 per cent.	3 16.7 per cent.	1 5.5 per cent.	3 16.7 per cent.
44 cases—no asthma	17 38.6 per cent.	18 40.9 per cent.	6 13.6 per cent.	3 6.8 per cent.
Total of 62 cases	28 45.1 per cent.	21 33.9 per cent.	7 11.3 per cent.	6 9.7 per cent.

Our spring extracts contain a mixture of the pollens of Agrostis alba (red top), Phleum pratense (timothy), Secale cereale (rye), and Dactylis glomerata (orchard grass; the autumnal type consists only of the two varieties of ragweed, Ambrosia artemisæfolia and A. trifida.

These vaccines have been used by ourselves and by other physicians kindly cooperating with us in the treatment of sixty-two patients.

One patient was apparently cured after treatment continued during both spring and autumn of two consecutive years. In the fourth year, however, the symptoms returned.

Another patient who was only partially relieved, was found to be susceptible to wheat pollen. In the following season three doses of the "spring" vaccine to which wheat pollen extract had been added, effected complete immunity to the end of the season.

Another patient not completely relieved by the spring vaccine was found susceptible to daisy pollen. A special daisy vaccine was prepared and the administration of a single dose brought complete relief.

Our results on the whole did not differ greatly from those obtained by other investigators since Noon's first report. In none of the cases did we consider the possibility of a superadded or even of a primary bacterial infection.

V. PARASPECIFIC TREATMENT; BACTERIAL VACCINES.

Farrington (148), Morrey (149), Lowdermilk (139), and more recently Strouse and Frank (150) have published reports concerning the use of bacterial vaccines in the treatment of hay fever.

Farrington (148) believes that he was the first to

use autogenous vaccines in hay fever. After nasal symptoms had developed, a sterile platinum loop was passed up along the middle turbinates, and the film of secretion was transferred to two sterile agar tubes. The combined growths, without regard to identity of the bacteria, were washed off with normal saline solution; the bacteria were then killed by heat and the suspension was standardized. Farrington treated one case, in 1911, with most gratifying results. The next year he applied this treatment in twenty-five cases, with the following results:

Thirteen cured (eight had asthma).
Six markedly improved (five had asthma).
Three slightly improved (all had asthma).
Three failures (all had asthma).

Morrey (149) treated eight cases with bacterial vaccines, in 1911 and 1912, with encouraging results. His theory concerning the action of the vaccines was that they would be followed by a "strengthening of the nasal mucosa, so that the irritants, whatever they are, would be without effect."

Lowdermilk (139) used autogenous vaccines "in all cases complicated by the presence of a bacterial infection." The criteria of infection are not given. "Sometimes the vaccine was alternated with the toxin, and in others it was given afterward."

Strouse and Frank (150) report their experiences with bacterial vaccines used alone as well as in combination with pollen extracts. Astonishingly good results followed in every case.

It is entirely possible that paroxysmal sneezing may be caused by bacterial infection, and in such cases treatment with appropriate vaccines would, of course, be considered specific therapy. In cases, also, where local bacterial infection adds to the severity of the attacks, definite relief should likewise result theoretically from the use of bacterial vaccines. The importance of bacteria in hay fever, however, is probably slight, since in the majority of instances the nasal symptoms either subside or disappear at the end of the season.

How, then, can we explain the beneficial results which have been reported to follow the injection of bacterial suspensions?

Many observations have already accumulated in regard to the use of nonspecific proteins in the treatment of acute infections. The action of these substances is believed to depend upon their activity in mobilizing the antibodies (Jobling and Petersen, 151). Just how this explanation can be applied to the use of nonspecific proteins in hay fever is a question that apparently has not yet been discussed. If, as we believe, hay fever is due to the existence of substances corresponding to antibodies, a treatment which would mobilize the antibodies would increase rather than diminish susceptibility to the symptoms. As a matter of fact, however, definite amelioration of symptoms has followed the use of certain nonspecific protein substances, and these results cannot be ignored.

Rowland (152), in 1904, treated eleven cases of hay fever with diphtheria antitoxin, and relief followed in every case. It will be remembered that about this time the beneficial effects of diphtheria antitoxin in the treatment of asthma began to attract considerable attention. Unfortunately, a certain proportion of persons subject to hay fever and asthma are also hypersusceptible to horse proteins. And since a few patients died of anaphylactic shock within several minutes of the injection of antitoxin, the administration of horse serum to asthmatic persons has come to be considered unsafe.

The writer has had no personal experience with nonspecific proteins in the treatment of hay fever, but an observation with regard to one result of the administration of bacterial vaccines in common colds (153) may explain the beneficial effect exerted upon the symptoms of hay fever. In this paper (153) attention was called to the vasomotor effect of bacterial vaccines on the nasal mucosa. Sometimes within a few minutes of the injection the membranes begin to shrink and within a short time, especially after a severe reaction, the dryness of the nostrils is so marked that there may be considerable discomfort. With an appropriate dose this contraction of the membranes affords a relief which may last for several days.

It may be remarked here that similar relief has been noted after atropine and epinephrine (Sajous, 71, Somers, 70a, etc.), the benefit being coincident with the shrinking of the nasal mucosa and apparently dependent thereupon. The inhalation of menthol has the same effect.

The suggestion forces itself upon us that, whether or not the effect of bacterial vaccines in hay fever is due to a specific response, the result depends upon the local effect upon the mucous membranes. In the light of Goodale's (145b) recent observations, it is possible that only those persons will experience contraction of the nasal mucosa who are specifically sensitized locally. Thus the local astringent effect of the vaccine may not be really nonspecific; it may, on the contrary, be a specific reaction with a nonspecific effect in addition, the latter being a purely physiological effect—a vasomotor stimulation resulting in the contraction of the capillaries, rendering them less permeable and likewise removing most of the secretion in which the pollens are ordinarily digested.

That a specific reaction is necessary is attested by the fact that persons susceptible to pollen of one variety—daisy, for instance—are not benefited by the extract of another variety—ragweed or timothy—to which they are not susceptible.

The explanation offered by the physical chemists is that the changed reactivity on the part of the tissues is due to an alteration in the aggregation of particles. One of the hopes physical chemistry has been holding out to us for several years is that we shall some time be able to control the colloidal state of the body fluids to such an extent that many abnormal physiological processes may be prevented or brought back to normal by very simple means. The administration of calcium lactate in hay fever is a move in this direction. Some of the work upon acidosis seems to be aimed in this direction. It is very depressing, however, to find that so much of the literature sounds like the late "uric acid theory" with merely the titles changed.

GENERAL DISCUSSION.

It is now generally conceded that hay fever is the result of a more or less localized intoxication in persons sensitized to certain proteins. The protein

in question is most frequently a constituent of pollen, but any other protein coming in contact with the nasal mucous membrane may be the exciting cause.

We are indebted to the recent investigations upon anaphylactic phenomena for our knowledge, however imperfect, concerning the mechanism of hay fever. But we are still unable to account for the genesis of the anaphylactic state.

The observations reported by Dunbar (128), in 1911, are particularly interesting and suggestive. The theory that the acquisition of hypersusceptibility is due to an abnormal permeability of the mucous membranes and cuticle resulting from some vasomotor lesion was apparently original with Dunbar. He noted:

1. Although the predisposition to hay fever is frequently hereditary, the hypersusceptibility may also be acquired. The pathological condition of the nasal mucosa must indeed be very subtle if certain individuals inherit membranes permeable to ragweed pollen proteins, for instance, while others inherit membranes permeable only to certain grass pollens. The explanation in such cases would seem more plausible if the persons inheriting hay fever were generally subject to both spring and fall types, provided, of course, that they live in places where both types are prevalent.

2. Normal persons injected with pollen or pollen extracts do not acquire hay fever.

3. In the treatment of hay fever with pollantin, a number of patients have acquired not only local but general hypersusceptibility to horse serum; on the other hand, the instillation of horse serum into the eyes or nostrils of normal persons has not resulted even in local sensitization in any case.

In his arguments against the anaphylactic theory, Dunbar (128) in 1913 stated that he had repeatedly observed that persons living in Germany who had never been in America, and thus had never come into contact with the pollen of golden rod or ragweed, acquired hay fever at the first contact with such pollen protein (*Jour. Hyg.*, 1913, p. 124). No details of this observation are given. Presumably it may be taken at its face value, but considering the possibilities of dried pollen carried in clothing, packed in trunks, etc., and the fact that only fourteen days are necessary to establish the hypersensitive state, it is difficult to accept without question the statement that these persons had never had a chance to become sensitized previous to the attack.

I have had occasion personally to observe one hay fever patient in whom no hereditary influence has been found. In consideration of the fact, however, that throughout childhood this person suffered frequently from nosebleed, it appears that either the bloodvessels in the nose were very thinly covered, or the mucous membrane was what Dunbar calls "abnormally permeable." It seems possible that in this case at least, the sensitized state may have been acquired by the penetration of proteins through the mucous membrane. This supposition is strengthened by the fact that the patient in question has hay fever from early spring until frost, and even in the winter she has periods of sneezing which may be traced to particles of protein floating in the air.

Furthermore, this theory of an "abnormally permeable membrane" may explain the apparent benefit of such local treatment as that advocated by Hollopeter (103). It does seem possible that the "scrubbing process" used by this author may render the membrane less permeable, or at least so alter its character that it becomes more like the cutaneous epithelium. Similar treatment in the form of vibratory massage, etc., has been reported by other writers (Urbantschitch 101), (Denker 102), (E. W. Wright 68), and the results appear to be satisfactory in a certain proportion of cases.

SUGGESTED PLAN OF TREATMENT.

Preliminary.—First, a thorough rhinoscopic examination of the nose is made and any condition requiring surgical treatment receives proper attention.

Diagnosis.—In the meantime, a diagnosis is made with regard to the varieties of pollen to which the patient is susceptible. The test material may be a pollen extract or may consist merely of the dried pollen.

A slight abrasion or scarification is made through the external layers of the skin. Upon this is spread a tiny quantity of moistened pollen. It will be found interesting to observe the tests for two or three hours when possible. Frequently, within this time, the reactions will be quite distinct. A light dry dressing is advisable to prevent rubbing by the clothing. Susceptible persons will show an area of redness beginning sometimes within a few minutes. The area may increase to a diameter of several inches. The abraded point when intense resembles a bee sting; that is, it is raised and has a white centre, and is accompanied with more or less intense itching. From four to six different pollens may be placed upon each forearm. Negative reactions may show immediately an area of redness, but this is due to traumatism and soon subsides.

While satisfactory diagnostic tests may result from applications of the pollens to the abraded skin, the intracutaneous injection of a definite amount of sterile extract is probably better technic, especially for studying the degree of sensitization.

In arriving at a diagnosis, the season during which the symptoms occur should receive due consideration. In spring and early summer the common grasses are most likely to produce the pollens responsible; in late summer and fall the symptoms are oftenest caused by the pollen of ragweed.

Although the patient himself may have an opinion regarding the plants with which the disease is associated, his conclusions are not always reliable. Many persons of the "early type," for instance, frequently attribute their symptoms to roses alone. As a matter of fact, the number of persons found to be susceptible to rose pollen is astonishingly small.

Since the number of pollens which have been demonstrated to cause hay fever is considerable, a botanical survey of the patient's habitual surroundings is advised.

As an aid in identifying the pollens inhaled by the patient, the author has suggested a special button consisting of a metal frame in which is held a microscope coverglass coated with the glycerin mixture used by Blackley (8). This button may

either be worn by the patient or be left in a properly protected place in the locality where his symptoms are most severe. After about twenty-four hours' exposure the coverglass is sent to the laboratory for microscopic examination and identification of the pollens.

Prophylaxis.—Prophylactic treatment may be begun two or three months before the hay fever season. An initial dose of extract containing 0.0025 mg. nitrogen is sufficient to elicit some immunizing response without producing disagreeable effects. Subsequent injections are given at five to seven day intervals. If the area of redness about the point of the first injection has been only slight, the second dose is increased to twice the original amount (0.005 mg.) No further increase is advised, and subsequent doses are increased to 0.01 mg. and 0.02 mg., except, of course, in the case of very sensitive persons, when the doses are reduced accordingly. Prophylactic injections are not successful in every case, and treatment throughout the season may be found necessary.

Treatment during the season.—Since the period of relief following an injection has been demonstrated to be variable (Ulrich, 140), each patient must be considered individually. If the symptoms can be held in abeyance for seven days after a dose of vaccine, there is no reason for making injections oftener than at seven day intervals. A few persons are relieved for only twenty-four hours; in such cases, daily doses are necessary. A fairly normal period of relief, however, is about five days, and if symptoms have not entirely disappeared for that length of time, either the diagnosis or the dose should be looked into more carefully. If the symptoms persist in spite of an apparently accurate diagnosis and specific treatment, bacterial vaccines are well worth trying. The writer has treated one case in which the administration of a stock vaccine containing the organisms most commonly present in the nose and throat, resulted in perfect relief for for more than three weeks.

IMMUNIZATION AND CURE.

The possibility of prophylaxis and definite cure are questions to which no final answer can be given at present. We do not yet know the exact mode of action involved in the injection of pollen extracts. If hay fever is a typical example of what we understand as the anaphylactic state, a subcutaneous injection of the pollen protein would reasonably result merely in a state of an anaphylaxis or a suspension of the hypersensitive condition until the material injected is eliminated. This assumption may explain the difference experienced by some persons in the duration of relief after an injection.

On the other hand, Noon (134) and Freeman (135), Cooke and Vander Veer (143b), etc., have reported a sufficient number of successful cases to indicate that it is possible to immunize specifically against hay fever. The only comment that seems justified at the present time is that although immunization seems possible in a certain percentage of cases, we have no adequate theory to explain the phenomenon.

Treatment during the season with pollen extracts is not difficult in its application, causes practically no discomfort to the patient, and has proved far more successful than any other method up to the present time.

ACUTE INTUSSUSCEPTION IN INFANTS.

Some Practical Points in the Diagnosis and Operative Treatment,

By Benjamin T. Tilton, M. D., F. A. C. S.,
New York,

Attending Surgeon, Babies' Ward, Post-Graduate Hospital.

The mortality of operation within twenty-four hours after the onset of acute intussusception in infants should not be materially higher than that of appendicitis operated upon in the same period, viz., practically nil. The fatal results are due almost always to two factors working separately or in conjunction, viz., failure to make the diagnosis early and faulty operative technic. As a matter of fact few acute abdominal conditions are easier to diagnose than intussusception, and its operative relief is in the great majority of the cases most simple. It is wholly unjustifiable that this condition in children should have a mortality in the neighborhood of forty per cent., when early diagnosis and proper operative treatment give such brilliant results.

The diagnosis of intussusception ought to be made in every case which presents the three cardinal symptoms: 1. Acute abdominal pain, shown by a sudden fit of crying or screaming associated with doubling up of the thighs on the abdomen; 2, vomiting which comes on soon after the onset of pain; and, 3, the passage of blood per rectum. The combination of these three symptoms in a child, especially in the first year, ought to suggest at once intussusception and lead to the search for other manifestations somewhat less constant and of less importance. This condition being one of intestinal obstruction, the practitioner may look in vain for certain signs usually associated with interruption of the fecal current, for example, abdominal distention. As a rule, the child's abdomen is normal in size during the first twenty-four hours, and except over the region of the invagination, presents nothing unusual on palpation. A tumor can usually be made out and should always be felt for. Should the child, on account of crying or straining, hold the abdominal muscles rigid, it may be impossible to feel the tumor until a few whiffs of anesthetic have been given. This may be done for the purposes of diagnosis only, or at the time of operation. Bimanual examination, through the rectum, may be an important aid in feeling the tumor. The characteristics of the tumor are its cylindrical shape and its transverse position in the abdomen. It lies usually above the iliac fossa and cannot be displaced laterally. The diagnostic value of a rectal examination lies in the possibility of feeling the apex of the intussusception, in the detection of blood which may not have escaped from the anus, and in facilitating the palpation of the tumor. It is therefore an advisable procedure, although the diagnosis can ordinarily be made before resorting to it.

In some cases the infant cries out with pain at intervals from increased peristalsis above the obstruction. These periodical exacerbations may become more and more frequent during the first twenty-four hours and in themselves suggest acute obstruction of the bowel. At other times, the child is apparently free from pain and may even go to sleep. In such cases the physician may be deceived as to the seriousness of the child's condition, particularly if his first visit is made during the quiescent period. A history, however, of a stormy onset, vomiting, and blood on the diapers should lead him to the right diagnosis, in spite of the child's apparent well being.

Symptoms like fecal vomiting, pale drawn face, cold extremities, distended tympanitic abdomen, exhaustion, etc., belong to the late stages when nothing can be expected from operative treatment. The diagnosis is then only too apparent and the favorable time for relief has gone by.

As regards differential diagnosis, the only condition in infants which practically comes into consideration is acute colitis. Here the onset is not so sudden nor so painful. Furthermore, the passages are more copious and contain bile, while in intussusception the movements are not large and contain only mucus and blood, because the obstruction at the point of invagination does not allow the passage of intestinal contents from above.

OPERATION.

The diagnosis of intussusception should be followed without delay by operation, at which certain fundamental principles must be observed to insure a favorable outcome. In the first place, the incision should be so placed that the surgeon's hand comes directly down to the portion of intestine involved; in other words, the tumor. This means the minimum amount of handling of intestine and traumatism from reaction, both of which are important factors in producing shock. I have found the best incision to be one that splits the rectus at the junction of its middle and inner third, and extends one third above and two thirds below the umbilicus. If possible, the tumor mass should be grasped with two fingers and brought out through the incision, and all further manipulations performed outside the abdomen. This shortens the process of reduction materially, allows temporary closure of the incision, and avoids the handling of other portions of the intestine. Fortunately, reduction of the intussusception is successful in between eighty and ninety per cent. of cases. Any other procedure beside reduction is so extremely unsatisfactory that every effort should be made to complete reduction. The apex of the intussusception should be pushed back and only light traction exerted. Care is required not to rupture the intestinal coat. If reduction fails, resection with end to end anastomosis probably offers the best chance of recovery, but the mortality is excessively high, as the case is usually a neglected one. The formation of an artificial anus is attended with practically one hundred per cent. mortality. When reduction is complete the intestine, if viable, should be promptly returned into the abdomen. Any attempt to prevent recurrence, such as anchoring or shortening the mesentery, means further intraabdominal manipulation and delay in getting the young patient off the table. Furthermore, the efficacy of any such procedure is doubtful. As a matter of experience recurrence takes place very rarely, and attempts to prevent it are based upon theoretical grounds. Closure of the abdominal wound requires special attention; many infants have recovered from the operation, but have acquired later a ventral hernia, on account of the straining from crying, etc. For this reason tension sutures of silkworm gut should be inserted through the skin and aponeurosis, in addition to the layer sutures. To combat the shock, the infant should have some form of external heat, such as an electric light bulb inside the blankets and salt solution per rectum or by hypodermoclysis. The latter is a convenient method in infants. It is important that the mother resume nursing at an early period and without disturbing the infant more than necessary. A dose of castor oil is the best means of carrying off the accumulated fecal contents and blood.

More general attention to these few salient points in the diagnosis and operative treatment of this not uncommon accident in infants will, I am convinced, reduce to a very low figure a mortality which even at the present time is far too high.

14 East Fifty-eighth Street.

ROENTGEN RAY THERAPEUTICS.

By A. Judson Quimby, M. D.,
New York,
And Will A. Quimby, M. D.,
New York.

The x ray has been used as a therapeutic agent since a short time after its discovery. Its exact status has never been defined sufficiently to class it among specific agents. That it modifies body metabolism, both locally and constitutionally, is recognized. So to control its properties as to produce definite results has been a problem with which the Röntgen therapeutist has wrestled since its introduction. Numerous mechanical and chemical devices have been brought forward as a means of controlling doses and modifying the character of the x rays.

Two methods of controlling the character of x rays in therapeutics have given greater or less success in the hands of different operators. One of these is the use of platinum barium cyanide in the form of a small pastel which is changed in color by the action of the x rays; this color change being the index of dose. Another advance is the introduction of the Coolidge tube, which gives relatively definite control of the uniformity and penetration of the x rays.

For some time, as a result of the observations in the treatment of leucemia and multiple carcinoma, together with certain types of skin lesions, we have been of the opinion that a considerable amount of the therapeutic effect of x rays is brought about through modification of the blood; a definite leucocytosis occurs, both locally and throughout the body, such as naturally results where traumatism or irritation occurs in a portion of the body. The local leucocytosis is also increased by the dilatation of the bloodvessels, which is probably due to the direct action of the x rays on the nerve endings, easily demonstrated by the frequent presence of a modified anesthesia or numbness in an extremity which has been exposed. A general leucocytosis takes place after a relatively small portion of the body has been exposed; this is probably a constitutional manifestation of a local reaction, and is further stimulated by waste products produced in the area treated. These substances are undoubtedly toxic material which are the special end products of the disintegrating diseased tissue, and may be so profuse as to produce alarming constitutional symptoms; this is most marked in the presence of a malignant mass or tuberculous glands While we do not have broken down disease tissue influencing the organism of the normal person, such as an x ray operator, the waste material of his normal tissue is sufficient to stimulate the multiplication of white blood cells.

Several röntgenologists who have watched their blood count have found a decided leucocytosis following undue exposure in connection with their duties. We have witnessed it in connection with the treatment of malignant growths and other types of lesions demanding use of the x ray. It would seem that even where the treatment is limited to a breast or stomach, a general leucocytosis will follow the x rays.

It has been our observation that there is a ten-

dency for local treatment of a malignant mass to modify favorably the development of a secondary growth in a distant part, such as mediastinal metastases; this is no doubt due to the general leucocytosis which increases the body resistance. This same phenomenon occurs after the hypodermic administration of animal and vegetable proteins and other extractives. This fact has encouraged the writers to be somewhat free in the exposure of the body of a patient in connection with the x ray treatment, maintaining thorough protection of the parts surrounding the primary area involved in a portion of the total exposure, and leaving it uncovered in the remainder of the total dose. Experience with the massive dose and the fractional doses of x ray, together with giving large doses within a short period or prolonging the time factor over an hour or more, has encouraged us to make the applications over the longer period of time.

While many theories have been propounded as to the action of x rays upon the organism, we regard the phenomenon as that of a physical bombardment of the atoms composing the molecules of the body cell, which bombardment renders the atom momentarily free, and so disorganizes the chemical constituents of the molecules composing the cell. We may illustrate this by the well known phenomenon of chemical action, which renders an atom nascent or free to combine with other elements or atoms of a like element. Heat will do this, and the result is coagulation of albumin. Electricity, if it does nothing else, can easily produce an electrolysis of the body tissue. That the rays can bring about chemical changes in the molecules of a similar character, is no doubt true, although the process is so slow that we have never been able to make it manifest within a brief period, and so produce absolute proof of chemical action.

Under ordinary conditions, the application of x rays is painless and even without sensation by the patient. If the current which produces the x rays is of very high voltage the patient will experience the same sensations as occur when they are placed near any electric current of high voltage; this is due to an electrostatic field which surrounds the wires and terminals which are charged. Recently our experience with excessively high voltage apparatus has demonstrated this phenomenon, even when the patient was placed some distance from the tube. Frequently the patient experiences the sensation of warmth in the area exposed; this is probably due to a slight hyperemia, which occurs at the time of exposure. The proximity of the body to high tension currents results in its being charged; this charge will increase or decrease the blood pressure. If the blood pressure is increased, frequently there is a sense of exhilaration and warmth throughout the body, which becomes so marked when the voltage is high as to produce free perspiration.

If the voltage used in the x ray tube is relatively low, it is not uncommon to see the patient go to sleep during the exposure; this is accompanied by a drop in blood pressure. The latter phenomenon is most common with the ordinary types of apparatus, which give a relatively low voltage; also the fact that most operators use a comparatively low x ray tube and low voltage current to excite it, results in the drop in pressure and tendency to drowsiness, which is a frequent experience among patients.

For many years it has been our practice to do x ray treatment with tubes of very high resistance, demanding a voltage of 80,000 to 100,000 volts. We have been able to increase this to several thousand volts in a circuit and to use tubes of excessively high vacuum, impossible to excite by ordinary apparatus. This places the patient in an electrostatic field that extends outward from the tube for a distance of several feet. Some peculiar phenomenon apparently occurs under these conditions, the exact character of which has been difficult to explain. One result has been that we have been able to administer tremendous doses of x ray without injuring the skin. In this work no method of filtering the x rays has been used.

Early x ray therapeutics was done with apparatus of very low capacity and tubes of low penetration. Experimenters demonstrated that with x rays so produced, about sixty per cent. of that which reached the skin was absorbed by the skin. Pfahler's introduction of the leather filter greatly reduced the percentage of x rays of low penetration which reached the skin, and enabled us to save it from much injury.

As the method of constructing high tension transformers and induction coils was improved, and the methods of pumping x ray tubes was perfected, it was found that by using a higher voltage, ranging up to 60,000 and 80,000, that a less percentage of x ray was absorbed by the skin and apparently deeper effects of therapeutic value were obtained.

Our first attempts at deep therapeutics were undertaken nine years ago, and consisted in the treatment of secondary metastases from the breast and malignant growths in stomachs. Having in mind the efficiency of high tubes with a sharp focus for the production of good definition in x ray plates, we selected for this work the best high vacuum tubes obtainable, and as the tendency is for tubes to drop in vacuum, always changed them frequently, trying to avoid the use of any given tube more than twice a day, to permit it to cool thoroughly before exposures. Recent experiments of Professor Scherer, of Cornell, have demonstrated that when a current is first introduced into the x ray tube it is not at its maximum penetration, but rises rapidly, then is carried at a maximum penetration until influenced by the heat generated and the gases liberated within it, following which there is a decline in the penetration of the x ray, until the heat is sufficient to lower the tube beyond efficiency; after this has occurred the tube must be set aside until cool, which permits the absorption of the excessive gases in the tube and a resulting rise in vacuum.

When the resistance of an x ray tube is comparatively low, it permits a free flow of secondary current, and an undue proportion of heat is produced more rapidly, dropping the vacuum of the tube. If we start our exposure with a tube already at a high vacuum, it maintains a greater resistance to the flow of current, for a much longer period, and a smaller amount of heat is produced in a given time, enabling us to carry the exposure much further; also the pro-

portion of deep penetrating rays produced is higher, and the amount necessary to absorb by filtering is less. In general, this principle applies to both the gas tube and the Coolidge tube; the latter is composed of the same elements as the gas tube and has the same susceptibility to heat generation and the resulting melting and vaporization of the metals.

The Coolidge tube has recently been accepted as the ideal tube in therapeutics. While its principle is good, its limitations are of the capacity of the elements composing it to resist heat. If we can overcome this, and at the same time maintain the uniformity of delivery, one of our great problems will be solved. In our own experience the delicacy of the metal composing the terminals has been a serious impediment to using any tube and giving prolonged exposures in massive doses. Accidents are quite common as a result of these conditions, and it becomes a factor in the cost of maintaining a therapeutic equipment.

Frequently experimenters have exhibited and used air cooled and water cooled tubes, convincing themselves that these have overcome the impediments referred to above. Our observations have been that the resulting enthusiasm soon wanes and after a comparatively brief period the operators return to the normal standard tube, which, owing to its simplicity when properly handled, ultimately gives the most satisfactory results.

At this point it is well to say that experience is a far better guide to a definite technic which meets the indications of our practice than such superficial knowledge as can be obtained with regard to the management of x ray tubes from a mere description of apparatus or technic. Every röntgenologist who acquires success has his own individual peculiarities and methods of analyzing his cases and results. He must meet waves of optimism and pessimism among his associates, accept a series of one class and do his best with them, and shortly turn to another group. He is beset with the difficulties of acquiring a uniform general electric supply. Numerous manufacturers have brought forth types of apparatus, which are not standardized. Because of these varying factors no method of exact measurements has been presented which is a success; if x rays could be measured out of a bottle, after having met the standard requirements of the U. S. Pharmacopœia, the x ray specialist could be a technician in fact as well as in theory.

The extensive and special apparatus required, and the close application to study of its peculiarities, and the numerous details in connection with röntgenography and röntgenotherapeutics have produced the professional röntgenologist. After prolonged experience in teaching the primitive elements of röntgenology, and after having followed the later development of a number of x ray specialists, we have concluded that to succeed and overcome all of these difculties has demanded a type of individual within the profession who is primarily a mechanic, and secondarily a clinician; one who can be a machinist in fact, and a therapeutist in theory.

It is interesting to study the personality of the entire group of representative röntgenologists of the profession; they are practically a class by themselves. They are serious minded, yet at the same time they assume the risks in connection with their work light heartedly. Many of the old group have succumbed to injuries from x ray burns. Not a few who have experienced the discomforts of röntgen dermatitis are living, but are exercising the precautions necessary to save them from further injury.

The precautions essential with regard to the care of the operator in protecting himself from the dangerous consequences of exposure to x rays, has led to many methods of limiting the field to that part of the patient's body which it is essential to expose. The introduction of protective devices, such as lead sheets and lead glass and rubber, and their persistent use has been a decided success; however, we have made an effort thoroughly to eliminate the dangers derived from minute exposures. Experiments have convinced us that thorough protection can be derived only from at least two cm. of lead or its equivalent in other metals. The equivalent is easily obtained by comparison of the atomic weight of the element. We have found iron as good a protection as lead, but demanding about twice the thickness, which is compensated for by its relatively low price and greater tensile strength, a factor when constructing heavy partitions.

In experimenting with very high tension currents in the production of x rays, we have been led to believe that the greater portion of the element of danger to the operator and patient is removed by maintaining a field of very high tension surging current around the tube; future developments will prove the value of this method. We have seen some prolonged exposures without protection; exposures continuing day after day for months, without dermatitis. Just how far this can be carried remains to be proved and justifies future study.

Our observation has been that where large doses of x rays are being administered, it is consistent policy to exercise control over the excretory functions, instructing patients to take thorough precautions with regard to managing the bowels, etc.; in addition, we believe that some form of physical therapeutics may be judiciously used, such as high tension electrical applications, massage, or light, or the several methods combined. Several times in our experience, pronounced x ray reactions which manifested dangerous symptoms, have been promptly controlled and rendered harmless by such therapeutic measures.

Recently it has been our practice to instruct the patients to bathe the parts exposed in an alkaline solution, as suggested by Doctor Dodd, of Boston, whenever any signs of reaction were manifested; it is a precaution that is sometimes of benefit. If we can obviate all risks of dangerous dermatitis to the operator and patient in the future, by improvement in devices which will select and control the penetrating rays, we feel that x ray therapeutics will be tremendously broadened. It now exceeds all the expectations of the earlier operators, and if the use of high voltage surging currents, as suggested in this paper, proves to be a step in that direction we shall be gratified.

OCCUPATIONAL THECITIS.

By Adolph Cohn, M. D.,
Philadelphia,
Assistant Orthopedist, Medico-Chirurgical Hospital; Clinical Assistant in Orthopedics, Polyclinic Hospital.

In view of the recent widespread adoption of workmen's compensation laws, a condition has presented itself to my attention that merits consideration, namely, thecitis of the flexor and extensor tendons of the thumb and fingers of the right hand, as a result of occupational conditions.

Etiology. I have observed a number of cases in men and women engaged in occupations requiring the use of heavy shears, such as sheet metal workers, tailors, dressmakers, also in workers who require the constant use of these tendons, such as pressers handling heavy sadirons. As predisposing causes, I believe that there is present in all these cases, a focus of infection such as tonsillitis, pyorrhea, sinusitis, gonorrheal urethritis, alveolar abscess, or gastrointestinal putrefaction. In cases where a focus of infection is not apparent, one will be found if looked for.

Pathology. The pathology of this condition is inflammation of the synovial sheath of the tendon with consequent exudate formation. This exudate is either absorbed or is transformed into connective tissue, the disease becoming chronic. In chronic cases the connective tissue contracts and results in interference with the free action of the tendon in its sheath. The pathological condition is due, I believe, to irritation from within, as a result of the focus of infection rendering the part unable to withstand the irritation from without due to constant use of the part. This produces an inflammation of the theca, interfering with the free motion of the tendon in its sheath. If the flexor tendons are affected we find the flexor sublimis digitorum, the flexor profundus digitorum, and the flexor longus pollicis affected simultaneously; since these three tendons lie in the same synovial sheath when they pass under the anterior annular ligament to be distributed to the thumb and fingers respectively. If the extensor tendons are affected, then we find that the extensor ossis metacarpi pollicis and the extensor primi internodi pollicis are affected. The extensors are more frequently affected than the flexors.

Symptoms. This condition may be acute or chronic. In the acute cases the patient complains of pain in the region of the affected tendon; most frequently about the radial side of the wrist (right side) on the extensor surface. This pain is aggravated by abduction and adduction of the thumb, and, if the flexor tendons are affected, by flexion of the wrist; in one case I saw, the wrist could not be flexed and the flexor tendons seemed to be in spasm. This pain is unaffected by time of day or by weather. In the early as well as in the late stage a friction or grating sound can be elicited. Swelling, if present, is slight. The temperature is normal. In nearly all these cases, some focus of infection may be found, the most common being pyorrhea or tonsillitis, although sinusitis plays a greater role than is generally suspected. Other sources of infection may be gonorrheal urethritis, alveolar abscess, gastrointestinal putrefaction, and recurrent furunculosis. The patients are unable to work and therefore must be looked after by their employers. It is here that I want to call the attention of physicians who examine for industrial concerns, to the importance of removing any focus of infection that may be present in any of their employees, present or prospective, thus safeguarding the health of the employees and the pocketbooks of the employers.

Chronic cases present much the same symptoms as acute cases, except that the pain is more of an ache and is aggravated by work. It is not as easily benefited by rest from work and is more severe at night. Some nodular swelling may be present along the course of the tendon sheaths. The general health of the patients as a rule is unaffected, although occasionally we find them poorly nourished and somewhat anemic, owing probably to the underlying cause or infective foci.

Case I. Miss S., age twenty-four years, dressmaker; family history, negative; medical history, frequent attacks of tonsillitis. Had had trouble with her teeth. Present illness: For the past few days patient was compelled to stop work because of pain along the radial surface of the right wrist on the extensor surface. It was a dull boring pain and the patient described it as being more like an ache. She stated that the pain was aggravated when she used her shears in cutting material. Examination revealed tenderness along the radial side of the right wrist on the extensor surface. Pain was increased on adduction or abduction of the thumb; movements of the wrist did not affect the pain. There was no swelling; temperature was normal. Examination of the throat showed the tonsils ragged and the pharynx congested; while the mouth showed several decayed teeth and pyorrhea.

Case II. Mr. L., age thirty-two years, sheet metal worker; was required to cut through heavy metal, necessitating the use of heavy shears. Family history negative. Medical history: Had had an abscess on the cheek several months ago. No history of trouble with nose or throat; no Neisserian infection. Present illness: Complained of pain along the radial side of the right wrist on the extensor surface, aggravated by abduction and adduction of the thumb. Had not been working for several weeks because of pain while using the shears. Examination showed tenderness along the radial side of the wrist (right) on the extensor surface; no swelling. A grating sound was elicited when the thumb was abducted or adducted; pain was also increased by these movements, but was unaffected by movements of the fingers. Examination of the nose and throat was negative; the teeth, however, were in poor condition. (This case I saw at the Polyclinic Hospital and am indebted to Dr. James K. Young for permission to publish it.)

Case III. Mr. W., aged forty-seven years, musician until some months ago; at present, a cutter of aprons. Family history, negative. Medical history: Played a wind instrument until twenty-five years ago, at which time he had a hemorrhage from lung (?) and was advised to give up the instrument. He then played the violin and piano, and was never troubled with pain in his arm except for an occasional tired feeling in his elbow. He was compelled to do something else for a living and he became a cutter of aprons, this requiring the use of heavy shears. Present illness: Complained of pain along the radial side of the right wrist on the extensor surface; also along the flexor surface of the wrist. Had had this pain for about one week. Examination showed tenderness about the flexor surface of the wrist; also on the extensor surface along the radial side. Pain was aggravated by abduction and adduction of the thumb and by movements of the fingers. Nose and throat negative, but teeth were in poor condition and gums showed pyorrhea.

Case IV. Mr. K., aged forty-five years, presser, had had pain along the lower part of the flexor surface of the forearm for the past six months, also sore throat and trouble with teeth. Movements of the wrist and thumb aggravated the pain. He must stop working every once in a while because he was unable to continue at work owing to pain in the lower part of the forearm. He had been a presser

a great many years, but never had trouble with his hand previous to his sore throat attack. Examination showed tenderness along the flexor surface of the forearm (lower part). Grating sound could be elicited by having patient move fingers, alternately flexing and extending them. Pain was aggravated by these movements.

Case V. L. G., aged forty years, tailor, had pain in the left wrist on the radial side. Pain worse when working, which consisted chiefly of pressing clothes, although he did a good bit of cutting with scissors. Patient was left handed, being unable to use the right hand in working. Had had this pain for nine weeks and had been unable to work during the greater part of this time. Pain was unaffected by time of day or weather, becoming worse only after use. He had no pain in the right wrist. No history of tonsillitis; teeth decayed and pyorrhea present. Throat negative, except for slight pharyngitis. Examination showed the right wrist normal and unaffected. In the left wrist, pain on motion of thumb and wrist, particularly abduction of the wrist. No swelling nor discoloration. Some crepitation.

These are but a few out of a large number of these cases that I have observed.

Diagnosis. The diagnosis is simple: A history of some focus of infection, particularly pyorrhea; occupation such as dressmaker, tailor, presser; right side if patient is right handed; characteristic pain affected by movements of the thumb if the extensors are affected, and by movements of the wrist and fingers if the flexors are affected. Temperature is normal.

Differential diagnosis. From tuberculous thecitis, by a history of tuberculosis, fever, longer duration, can occur in any occupation or irrespective of occupation. From suppurative thecitis—by fever, swelling, history of digital or palmar abscess. From osteitis, periostitis, or osteoperiostitis, by swelling, fever, history of injury, and x ray. From arthritis by limited or impaired motion of the joint, history, and x ray.

Prognosis is good if treated early and the focus of infection is eradicated. If neglected, a chronic thecitis results, which may terminate in a spasm of the muscle and render the wrist useless. Treated early, these cases get well in two weeks to a month.

Treatment. Prophylaxis involves removal of the focus of infection. Cure demands rest of the part and cessation of work until part is given a chance to recover itself. Locally, I prescribe an ointment containing:

℞ Tincturæ iodi, ...3i;
Unguenti ichthyolis, .
Unguenti belladonnæ, } .....āā 5ss.
M. fiat unguentum.

Of great benefit locally in addition is baking. Iodine is applied to the part and the part is baked for about ten minutes. I believe the congestion due to the heat brings a larger number of leucocytes to the part, these carrying off the exudate. In the early part of the treatment massage should not be used, but may be tried with benefit later, especially in the chronic cases. Internally I prescribe syrupus ferri iodidi, half a dram, and syrup of hydriodic acid dilute, half a dram, for the benefit of the iodine action on exudates as well as for its tonic effect. When these patients get well, it is of benefit to have them wear some kind of support over the wrist to take the strain off the tendons. This may be a leather wrist band or preferably an elastic sleeve.

CONCLUSIONS.

1. Thecitis is common as a result of occupations such as dressmaking, cutting, and pressing.

2. Always look for and eradicate any focus of infection.

3. Extensors are more frequently affected than flexors, on the whole. Extensors are also more commonly affected in those using shears, while the flexors are more commonly affected in those using sadirons.

4. Symptoms clear up in a short time under proper treatment, while, untreated, they become chronic and result in impaired motion with impaired function.

937 North Eighth Street.

PSYCHOLOGY OF THE FADDIST.

By B. S. Talmey, M. D.,
New York.

The depth of the mental operations of the faddist or the fanatic can be fathomed only by a thorough study in detail of the main principle of the new psychology of the unconscious. The genetic standpoint of this psychology regards the multiplicity of instincts as issuing from a relative unity, the primal libido, or the continuous life impulse, the *élan vital* of Bergson or the *Wille* of Schopenhauer.

The most intelligible articulation of this primal libido is sex attraction. It is the outflow of the immortality implanted in the depth of all organic life. Erotic libido represents the will to live, the continuous life impulse, centred in the preservation of the individual and through it of the race.

The basis of the new psychology of the unconscious is the axiomatic truth that every man loves women, i. e., the female of his species. The majority of men may pass through their allotted three score and ten years of life without ever having loved a woman, a certain woman, but they all love women. In the same way, every woman loves men, i. e., the male of her species. Those who do not are simply degenerates.

The new psychology also accepts the empiric knowledge as a truism that this attraction of the sexes is found already in the very young animal before it is ripe for sexual activity and before it shows other sex manifestations.[1] The new psychology teaches that every child is sexually attached to its parent of the opposite sex. The little boy does not love his mother only as a parent who administers to all his needs, but is attracted to her also for the reason that she is the first female of his species he comes in contact with. The little girl's love for her father is not based on filial love alone, but also upon sex attraction. The father is the first male of her species she came in contact with and with whom she associates daily. This erotic attraction remains intact till the child reaches school age. It then escapes from conscious control and remains dormant till the age of puberty. At this period the old attachment

[1] The best way the farmer, who owns a pullet and receives another young fowl in the barnyard, can tell the sex of the newcomer is by the behavior of the two birds. If the two young fowls fight, then the newcomer is also a pullet, i. e., of the same sex. If the newcomer is of the male sex, there will be no fight. The two sexes attract each other already at a time when no other sex manifestations are in sight as yet. The human infant makes no exception to this rule.

returns to the surface, and this time with the conscious desire for the exercise of the newly acquired sexual powers with the beloved individuals.

During the intervening period from infancy to puberty, however, the child has learned that incest is the greatest abomination in the sight of God and man. Nothing, not even murder, shocks our moral sense more than an incestuous occurrence in the community. Hence, as puberty is attained, a typical conflict arises in the moral nature of the adolescent child between the social cultural demands and the infantile tendencies. The child is puzzled in the midst of conflicting impulses and ideas. The desires are hence diverted from the sexual territory into associated functions. If this operation succeeds without injury to the adaptation of the individual, it is called sublimation. By sublimation the infantile tendencies are disguised and concealed and pass recognition.

Such diversion of the sexual libido from the erotic territory into other functions is found when religious fanaticism is analyzed. The transference of sexuality into religiosity serves to soothe the individual's conscience. There is a certain affinity between eroticism and religion. Religious worship is an emanation of sex worship. All early creeds consisted in the worship of the generative principle (See *Love*, p. 2). Libido harbors a metaphysical element and is hence akin to the metaphysics of religion. This relationship between libido and religion has the effect that the psychological projection of the sexual is often directed toward the religious. The diverted erotic desires create compensations in the form of religious activity. Religious fanaticism is thus, as a rule, an extreme expression of exaggerated eroticism. All strong emotions, however, nonsexual, represent the displacement of the erotic into other channels.

Where the attempts of the psychological projection do not entirely succeed, if there is a certain failure of adaptation, the individual takes his refuge in repression. By repression, the desires are, in a way, stored away, incapsulated into subconsciousness. Repression is thus the normal mechanism by which nature protects the individual from painful feelings and helps him overcome the wounds and conflicts taking place in his soul.

By repression the isolated idea forms a point of crystallization around which all other corresponding ideas gather and form psychic groups or "complexes." Thus in the realm of the erotic it has been found that every boy harbors in his subconsciousness the "Œdipus complex" (Œdipus married his mother), or a certain erotic attachment to his mother, and every girl harbors in the subconscious strata of her soul the "Electra complex" (Electra, out of love to her father, Agamemnon, incited her brother, Orestes, to avenge her father's death by assassinating their mother Clytemnestra), or an erotic love for her father. The complex, or the important group of ideas with the feelings and emotions clustered around them, remains submerged in the unconscious below the threshold of consciousness, and the repressed desires never rise again to disturb the individual's composure.

But nature does not always effect a perfect adaptation of the psyche to society's mandates. It sometimes only succeeds in isolating the emotions psychically to repress them incompletely into the unconscious. A "symbolical reminiscence" is retained. Certain memory pictures irradiate from the subconscious into the conscious strata of the psyche. If no free outlet is given to the symbolical reminiscence, a struggle between the wish to forget and the striving of the idea to come to the surface results in a compromise, in the transformation into a hysterical symptom. The symptom represents the deviation of the wish fulfillment into other channels. It is the individual's "defense" against the reminiscence, gleaming through from the complexes. Behind the symptom the psychanalyst often discovers in the son the erotic love to the mother, or the Œdipus complex, and in the daughter the erotic love to the father, or the Electra complex. The symptom is the defense action against the symbolical reminiscence of the infantile erotic attachments. The repressed contents are set forth into seeming objectivity.

By the study of the abnormal—and the best way to gain an adequate knowledge in these spheres is by the study of the abnormal—it has been found that hysterical symptoms represent the defense against tendencies with which the individual feels unable to cope. The basis and origin of the various symptoms of hysterical individuals are the unfulfilled desires and wishes. The symptoms are developed in order to conceal and overcompensate for the impossible situation. The gravity of the symptom is determined by the individual's reactions toward the tendencies of his own constitution.

From the psychological point of view the most frequent hysterical symptom is fanaticism, which also represents the defense against some complex. The general activities and reactions of man can thus be easily understood. The expresions or manifestations of the psyche are not lawless or unmotivated. The unfulfilled wishes and desires are the determinants at the root of human conduct. They explain the phenomena of conduct in human life. Objectionable desires and wishes are deflected into other channels and are then expressed in prejudices and attitudes of conduct. The unconscious tendencies are the underlying motives and determinants of the individual's attitude. When the attitude of conduct reaches its climax, it becomes fanaticism.[2] When an individual exhibits an exaggerated interest or places an overemphasis upon an idea or situation, he is concealing his weaknesses.

The faddist is almost invariably defending himself against a complex that stands in inverse relation to his eccentricity. The normal individual, without exaggerated desires and with a sane, healthy education, does not harbor complexes and never becomes a real fanatic. The defense symptom is the basis for the life conduct of the fanatic or the crank.

[2]It may be laid down as a rule that every faddist harbors in his subconsciousness a complex in direct opposition to his fad. "He who befouls others befouls by his own foulness," *"Kol haposul bemumo posul,"* says the *Talmud* (Kidushin, 70a). We insinuate those faults in others which we ourselves possess. We pretend to and really think that we detest things which in our subconsciousness we greatly desire. Love may turn into hatred but never into indifference. The man, whose wife has left hm to go to live with her mother, remains indifferent if he does not love her any longer. If he still desires her, this sensual love may turn into hatred, and he goes to her mother's house and kills her. His hatred attests his still overwhelming desires.

Behind every kind of fanaticism lies a conflict between natural tendencies and early teachings. The conflict leads to repression and hence to the formation of a complex. The symbolical reminiscence of this complex leads then to a fanatic expression. Behind the exaggerated defense reactions in fanaticism can almost invariably be detected the controlling power of unconscious desires over thoughts and acts.

A look at the purist will show that, as a rule, he harbors in his subconsciousness the purity or obscenity complex. If parents did not so scrupulously hide their nudity before their children, if the mother took her little boy into the bath room every time she took a bath, or the father his little daughter each time he took a bath, beginning these practices before the children had any adequate idea of the meaning of sex, the children would grow up without finding anything obscene in the nude body, nude picture, or nude statue.

But from our early infancy we have been taught the indecency of the nude. We have been taught that everything connected with sex is unclean and obscene, that erotic thoughts are unholy and sinful, that erotic emotions are vile and wicked, that erotic activities are low and vulgar, and that sex is altogether the work of Satan. As puberty, with the germinating eroticism, is attained, a conflict is developed between nature and culture, between an essential biological necessity for the fulfillment of the ego and the authority of the early precepts which can see only shame in sex and denies what the ego cannot accord. The individual is aware of the inadequacy in the association of the primal emotions with those mental powers which have been developed because of the moral teachings, and a struggle begins between his weakness and his feelings of idealism. If the individual is able to overcome the obstacle in his life path which arose through the early perverted injunctions, then he develops normally. But if he either possesses exaggerated desires or too great an emphasis was laid upon his early lessons in purity, then he shrinks from the magnitude of the obstacle, and strives to repress the emotions and to eliminate them from consciousness. In this way the obscenity complex is created.

The fanatic purist who clamors the loudest against obscenity and who would entirely eradicate nudity from this world is in his nature a sensualist. Beneath the pretensions, or rather beneath the honest desire for purity and sinlessness lie very ordinary elements. His early faulty instruction and the injunctions he received against all things sensual come in conflict with his natural tendencies. He represses his desires and tendencies and thus forms the obscenity complex. The symbolical reminiscence requires then a defense, and this the individual seeks in his fad. The mania to look for obscenity where the normal individual would see none was produced as a defense against sensual wishes and desires. The thwarted impulse for matters sensual, such as obscene books, or pictures and statues of the nude takes another outlet. He seeks freedom from the obscenity wish by losing himself in what he considers social service. The pseudovirtuous indignation over the nude or obscene is only an outlet for his natural ardor for the obscene and nude. In his eagerness to find a defense against his unconscious tendencies, his fantasy becomes twisted and distorted. Everything in life bears an obscene stamp. His fanaticism in the detection and persecution of the nude and obscene has its origin and significance in his obscenity complex. His loud clamor against the sacrilegious evil of the representation of the obscene in literature and art is only the defensive fence he has built around himself against his unconscious desires for the very things he is clamoring against.

Persons strongly dowered with sexuality, experiencing in the highest degree the great force of sexual needs, spontaneously exhibit more shame and purity than others. They are not necessarily hypocrites. They merely wish to defend themselves against the craving for wish fulfillment.

The complexes and the defenses are artificial products created through the conflicts between the faulty early teachings and the later emotions. They are not found in primitive man or in the child. If the child received a sane conception of sex, if it learned that sex activity is no more shameful than the activity of eating or drinking, that if the sight of sexual activity is unesthetic, it is no more unesthetic than the act of micturition or defecation of which nobody is ashamed, then the conflicts of puberty would never appear even in highly sensual natures, and without a conflict there is no repression, complex, or defense action. But every mention of sex being tabooed in the majority of refined families, a certain conflict in highly emotional natures is unavoidable, and a variety of complexes, based upon sexual emotions, is the result.

The turbulent zealot, the perverted morality hunter, who is shocked and hurt over the sins of the scarlet woman and plumes herself upon her self placed halo and prides herself upon her superiority, has in her makeup certain traits of her she hates so relentlessly. She is by nature a varietist. Under different circumstances she herself would have become a priestess of Venus vulgivaga. But being brought up in surroundings where everything sexual was religiously proscribed at the time of puberty, a conflict arose between her appetite for variety and the early impressions. The desires were then repressed and the prostitution complex was formed. The symbolical reminiscence of the cravings toward variety determines her sanctimonious behavior. The prosecuting zeal of the reformer represents nothing but the defense action against the symbolic reminiscence.

Another complex based on sex hunger is feminism. The sexual varietist does not always turn to low vice hunting in the defense of the symbolical reminiscence. If she was brought up as the clinging vine variety, and at the time of full maturity does not find the right support to cling to, the thwarted exaggerated eroticism is repressed, and the militantism conflict is created. As a defense against the reminiscence of this complex, the woman turns to sex antagonism or militantism. Behind the desire for political equality dwells the desire for sexual equality, whereby the ungratified primitive instincts can find a natural outlet.

All strong emotions, however nonsexual, tend to

overflow into sexual channels, and strong sexual emotions often turn to nonsexual social activities. Exaggerated settlement work or sick nursing often represents the transmutation of sexual energy into channels which act as sexual equivalents. Not only in the realm of sex, but every exaggeration in conduct has as its basis another exaggeration, either of the natural desires or of the early inculcations. The greater the exaggeration, the more pronounced is the conflict and the more salient the adaptation.

The rabid prohibitionist is defending himself against the drink complex. In his youth he received strict injunctions against the saloon. If by inheritance an exaggerated desire appears later on, the early injunctions come in conflict with his exaggerated cravings for liquor. The desires are then subjected to repression, and a drink complex ensues. Against the symbolical reminiscence of this complex prohibition is seized as a defense action. A person endowed with an irresistible desire for drink becomes either a confirmed drunkard or a screeching prohibitionist. There is a reason for the existence of a Carrie Nation.

The fanatic antivivisectionist harbors in his nature certain features of the sadist. He is by nature cruel. But early in his youth he received the mandates of parents and teachers to be kind to animals. These teachings come in conflict with the cruel tendencies in his character. The cruel emotions are repressed, and a cruelty complex is formed. The defense against the symbolical reminiscence of the cruelty complex determines his fanatic raving against vivisection. He is cruel enough to sacrifice millions of sick children if only his beloved rabbits are safe.

The rabid antisemite—any Gentile of normal constitution may like, dislike, or be indifferent toward the Jew, but he is never a fanatic antisemite—is harboring in his subconsciousness the "Shylock complex." In his youth he was taught that every Jew was a mean, sordid, avaricious, stingy, covetous, grasping creature always hungry for the Gentile's pound of flesh, a veritable Shylock who ought to be despised, hated, and shunned. When the future antisemite reaches adult age he finds that he himself is afflicted with an inordinate desire for worldly possessions. These desires clash with his early precepts to hate and despise the person dominated by such desires. The tendencies are thereupon repressed, and the repression creates the "Shylock complex." The symbolic reminiscence of this complex requires a certain defense action, and the subject screens himself behind his raging antisemitism, which does not always entirely cover the complex. Under favorable conditions the rabid antisemite outshylocks Shylock.

Even the fanatic socialist shelters in his subconsciousness a certain complex which may be called the "individualistic complex." His early lessons of conduct, just as the lessons of any other child in Christian countries, were based upon the Biblical precepts of social justice. When he grows up to manhood he finds that he is by nature an egotistic individualist who cares for nobody but himself. This pronounced egotism comes in collision with his early precepts to consider society first and himself second. Thereupon the egotistic tendencies are repressed, and the repression creates the "individualism complex." The symbolic reminiscence of this complex demands a certain defense, and the individual hides behind socialism. When the fanatic socialist becomes himself a capitalist he betrays his complex by being more exacting toward labor than the born capitalist.

The anarchist shelters in his unconscious psyche the "oppression complex." Generally he was brought up in a country ruled by tyrannical laws and is himself by nature a tyrant. But he was reared in a home atmosphere of silent rebellion against tyranny. The love of liberty and freedom was sung and preached to him on every occasion. When he reaches adolescence he finds that the traits of the tyrant dwell in his character, that he is intolerant toward the acts and opinions of others, and that if he had the power he would be a little czar in disguise. This love of power clashes with the inculcations of sweet liberty for everybody. The inordinate desires for power are thereupon repressed, and the "oppression complex" is formed. The symbolical reminiscence of this complex leads to the seizure upon anarchy as a defense. The anarchistic doctrines hide from the individual himself his deep seated tyrannical inclinations, which appear at the surface when the anarchist himself is invested with authority in any office or occupation.

The course of development of every kind of fanaticism, just as the development of the hysterical symptom with which fanaticism has certain resemblances, is thus as follows: First, certain exaggerated inculcations of conduct are a condition *sine qua non*. Second, there must exist certain natural inherited desires or traits of character, antagonistic to the inculcations. The third step is the conflict between nature and nurture, between the desires and the lessons. The fourth step is the repression of the desires. The fifth step is the formation of the complex. The sixth step is the defense against a symbolical reminiscence of the complex. The defense actions manifest themselves either in hysterical symptoms or in fads. Two things are of absolute necessity for the development of the fanatic or the faddist, exaggerated precepts and exaggerated desires. Without either, there is no conflict, no repression, no complex, no reminiscences, no defense, and hence no fad.

All these psychic traits of the faddist are manifested by the study of the abnormal manifestations of erotic libido. Libido, in general, is the life principle permeating entire nature and upholding the same. All strong emotions take their rise from this libido and are uncovered and disclosed by a close study of this creative principle in the universe.

12 West 123d Street.

Practical Notes on Blood Pressure.—George Van Ness Dearborn (*Medical Record*, Sept. 16, 1916) gives the results of 4,800 blood pressure measurements which justify his statement that readings must be taken every one or two minutes for a half hour or thereabouts and on several successive days in order to be accurate. Anxiety, excitement, emotion, or fright may cause high pressure readings.

IRITIS AND THE GENERAL PRACTITIONER.

By William L. Rhodes, M. D.,
Kansas City, Kansas,
Assistant Ophthalmologist, St. Margaret Hospital.

That many cases of iritis exist that are not diagnosed as such, and consequently receive little treatment or none at all, is undoubtedly true, especially in the practice of physicians away from the medical centres where there is abundant opportunity for the study of this condition.

Recently a case was referred to me which I will cite as an example.

Case. To a girl, ten years of age, giving a history of pain in the left eye, photophobia, excessive lacrymation, and a congestion of the sclera, the family doctor was called, and diagnosed the case as being "pink eye." He prescribed a mild wash, probably a boric acid solution, and told the child's parents to continue the medicine for a few days and the patient would be all right.

The inflammatory condition subsided in a few weeks, but the child couldn't see as well as formerly. Upon examining the eye with oblique illumination, and by means of the ophthalmoscope, I found that she had an annular posterior synechia, with an opacity of the crystalline lens; vision consisted in being able to count fingers at four feet in a strong light.

This case had been mistreated by the physician, who in all other lines of work is a very capable man; he failed to make the proper diagnosis, with the result that the patient has a permanent loss of vision in one eye. This, however, can be remedied by doing an iridotomy, thereby giving the patient some degree of vision through the artificial pupil made in the iris, but to date I have not been able to prevail upon the parents to allow this to be done.

We frequently observe this type of case in our charity hospitals, some being the result of improper treatment, some being neglected through lack of funds to pay a doctor, and still others who put more faith in patent eye medicines than they do in the medical profession, and who, after the damage is done, come to the hospital and expect the ophthalmologist to give them perfect vision.

I have just concluded the treatment of one of this type of patient, who, five weeks previously, had had an attack of iritis and for three weeks had used patent medicines in the hope that they would suffice and the patient would thereby save a doctor's bill. At the end of the third week she went to a local general practitioner, who treated her a few times and referred her to me. The inflammation has subsided after four weeks' treatment, with the result that she has a complete posterior synechia and an opacity of the crystalline lens, with a vision that consists of finger reading at one foot in a strong light.

This is a deplorable condition, but one over which neither the specialist nor the general practitioner has any control, the patient having lost her eye before she consulted a doctor, and having only herself to blame for loss of vision. It is possible to recover fairly good vision by doing an iridotomy as suggested in the case cited, but ordinarily the person who experiments with his own eye has not the intelligence to take advantage of his opportunity and consent to an operation.

Iritis may easily be confounded with a simple conjunctivitis, and a faulty diagnosis made, which later may bring both patient and physician to grief.

ETIOLOGY.

The causes of iritis may be either primary, as from a local gonorrheal ophthalmia, from traumatism, or frequently from infection of the iris from a corneal ulcer, or it may be secondary to constitutional disorders, as from a syphilitic infection, from a "rheumatic" source, or from a tuberculous condition. The rheumatic type has as its foci of infection diseased tonsils, diseased gums and teeth, and possibly a diseased prostate.

DIAGNOSIS.

The symptoms of iritis are typical. The color of the iris changes; it has a dull muddied appearance, the lustre is lost, as is also the characteristic striated appearance found in the healthy iris, while another frequent symptom is a fine meshwork of minute bloodvessels forming a halo around the cornea and perceptibly diminishing, the farther away from the cornea they are situated. This is nature's effort to furnish nourishment to the cornea and to carry off infectious matter, and should cause the physician no undue alarm. Miosis is in evidence, due partially to inflammation of the peripheral nerve filaments, and partially to hyperemia and spasm of the sphincter. The reaction of the pupil to light and to mydriatics is either diminished or lost, depending upon the severity of the infection and the length of time it has been in existence.

Posterior synechia, or an adhesion between the layer of pigment covering the posterior surface of the iris and the anterior surface of the lens capsule, soon makes itself manifest, provided that a mydriatic has not been used early in the course of the disease and kept up regularly. However, even with early treatment we frequently get an adhesion of at least a part of the iris and the anterior lens capsule.

The diagnosis of posterior synechia can be demonstrated by instilling a mydriatic into the affected eye, thereby producing an irregularity of the pupillary margin of the iris, showing the attachments quite plainly between the iris and the anterior lens capsule, provided, of course, that there is not an annular posterior synechia, in which case there will be no change in the pupil, as it adheres to the lens at all points of the pupillary margin.

The adhesions vary in size, some being broad and dense, while others are threadlike. The surface of the iris usually shows irregularities due to deposits of fibrin and the accumulation of exudative materials, while in some cases the formation of nodules is noticeable. In cases having annular posterior synechia we often find a false membrane, which varies in density, and completely occludes the region of the pupillary area.

In all cases of iritis a haziness of the cornea exists, due to the deposits on the posterior surface of Descemet's membrane. Changes also occur in the aqueous humor, due either to an exudate, blood, pus, or to a mild turbidity of the aqueous.

The subjective symptoms comprise pain, beginning in the eyeball and then spreading to the brow and temple. Photophobia is constant, while a de-

crease in visual power is a prominent symptom. The pain is intense in some cases, especially in the region of the supraorbital nerve, and is always worse at night. In some cases pain is noticeable in the teeth, and in the infraorbital and nasal regions, and causes additional discomfort to the patient.

The disturbance in vision is in direct proportion to the cloudiness of the media, and the extent of involvement of the posterior surface of Descemet's membrane. Later, should a posterior synechia occur, vision is decreased in proportion to the extent of the adhesions, and to the coexisting cloudiness of the lens capsule. In acute iritis, when the vision is considerably decreased, we may expect to find an extension of the disease to the ciliary body and the deeper structures, it being practically impossible in a great many cases to determine whether the iris alone is affected, or whether both iris and ciliary body are involved.

Transient myopia and astigmatism are noticeable in all cases of iritis, and are especially pronounced in the plastic type of the disease, even when thorough dilatation of the pupil has been obtained. According to some recent investigators, the corneal curvature is due chiefly to a perversion of the lens action from spastic accommodation as the result of ciliary irritation.

A tenderness of the globe is usually present in iritis, and is especially pronounced in the rheumatic type. Where tenderness is extremely severe, we may expect to find involvement of the ciliary body as well as of the iris.

Photophobia varies in degree in different cases; in some it is slight, while in others it is severe. In the rheumatic type the photophobia is usually less severe than in the syphilitic type, and clears up more quickly under treatment.

A "rheumatic" type of iritis usually attacks but one eye, while in a syphilitic iritis first one eye is involved, closely followed by the other, so that we can say with reasonable certainty that a double iritis is of syphilitic origin and treat accordingly. However, it is a good plan to have the diagnosis confirmed by a Wassermann or a colloidal gold test.

The pain in a rheumatic iritis is more severe than in the syphilitic type, but the photophobia is usually much greater in the latter, which responds more slowly to treatment.

TREATMENT.

The treatment of the rheumatic type of iritis consists in the early and frequent local use of atropine and dionin, together with hot, moist applications, while internally we give sodium salicylate in five to ten grain doses. Where the focus of infection is found to be in diseased tonsils, prompt improvement usually follows a tonsillectomy, the same being true where infection comes from diseased gums. After proper treatment has been instituted, the iritis subsides as the diseased condition of the gums improves.

The various ointments do very little good; in my opinion they are a disadvantage in that they keep the cornea gummed up with an oily coating which lessens the effect of the atropine.

The treatment of the syphilitic type of iritis is systematically the same as of a syphilitic manifestation in any other part of the body. Salvarsan intravenously, or neosalvarsan intraspinally, is of distinct advantage, while internally potassium iodide in increasing doses, combined with mercury in the form of an inunction, is the best treatment. Locally the use of atropine and dionin, and of hot moist applications is indicated.

It is a grave mistake to use the yellow oxide of mercury locally, and at the same time potassium iodide internally, on account of the precipitation of mercuric iodide, which occurs when the potassium iodide bearing tears comes in contact with the yellow oxide of mercury ointment. This will cause a flare up of all the symptoms and the patient will complain of increased distress.

Sodium salicylate in five grain doses, every three hours, will relieve the pain in most cases of iritis, and is of special benefit in the rheumatic type of the disease. Hot moist packs frequently used often give marked relief, and are indicated in all cases.

LABYRINTHINE INFLAMMATION.*

Secondary to Chronic Purulent Otitis Media,

By Charles B. Broder, A. B., M. D.,
New York,

Instructor in Laryngology, Polyclinic Hospital and Medical School; Adjunct Otolaryngologist, City Hospital; Visiting Ophthalmologist and Otologist, People's Hospital.

A study of the anatomy of the middle ear and of the structures in intimate relation to it, will convince us of the dangers incident to a chronic discharging ear. The tympanum is in direct contact with the cerebrum, the labyrinth, the jugular bulb, and the mastoid cells, and indirectly with the endocranial sinuses and the cerebellum.

An inflammation of the middle ear may readily involve a contiguous structure, especially if the condition is chronic or if drainage is interfered with, or if the infecting organism is of a virulent nature. In the cases reported, destruction of the labyrinth had followed a long standing purulent condition of the middle ear.

Case I. N. S., twenty-seven years of age, was admitted to my service at the People's Hospital on March 5, 1916, with a history of an intermittent discharge from both ears from youth. Hearing had always been poor; had suffered from occasional attacks of vertigo and tinnitus. For three weeks before entering the hospital, the discharge from the right ear became more abundant, with pain in the back of the ear and frontal and parietal headaches. In fact, the severity of the headaches induced him to seek relief. On admission, temperature was 101° F., pulse 120. The right external canal was filled with a quantity of fetid smelling pus, upon the removal of which no evidence of drum membrane was seen. There was complete deafness in the right ear, with a total absence of vestibular reaction. No response to high and low tuning forks, and Schwabach was heard in the opposite ear. No spontaneous nystagmus. Neither air compression nor aspiration in the right external auditory canal caused nystagmus. The blood count showed a leucocytosis of 20,000, polynuclear eighty-five per cent. Tenderness over the entire mastoid, with slight edema of the soft tissues. No disturbance of equilibrium. The left ear showed impaired hearing, but the labyrinth reacted to the physiological tests. Diagnosed as chronic purulent otitis media, with mastoiditis and latent suppurative labyrinthitis.

A radical mastoid operation was done. The mas-

*Read before the Clinical Society of the People's Hospital, May 10, 1916.

toid was filled with pus and granulations, the necrosis and softening extending to the sigmoid sinus and to the dura of the middle fossa. The dura over the tegmen antri was covered with granulations. The diseased cells were removed and the region between the semicircular canals was cleaned out and examined. No fistula was found. A portion of the stapes was seen in the recess of the oval window. A remnant of the malleus and part of the incus were found and removed. The promontory and round window were inspected. The granulations were removed from the tympanic cavity, the tube was curetted, and the posterior wound completely sewed up. Healing was normal. The complete deafness of the diseased ear, with the lack of response of the vestibular apparatus to stimulation, and the absence of labyrinthine symptoms of irritation indicated a chronic latent labyrinthine inflammation.

Case II. Mrs. M., aged forty years, admitted to People's Hospital, April 15, 1916, with a history of a discharging right ear since childhood. Had occasionally had pain on right side of head and over right mastoid, and occasional attacks of vertigo. Three weeks ago, she experienced severe pain in the diseased ear, with soreness over the mastoid, and bad headaches, particularly at night. The discharge became profuse from the external canal. Examination of the labyrinth showed complete destruction, as elicited by the total loss of hearing, with absence of caloric reaction and great shortening of the rotation after nystagmus toward the diseased side. There was no spontaneous nystagmus. Right ear inspection revealed absence of drum membrane, with the handle of the malleus isolated and loosely suspended. Abundant granulations sprung from the inner wall of the tympanum. Discharge profuse and fetid. Mastoid sensitive to pressure at the tip and antrum. The left ear had good hearing, with a normal response to the thermic and turning reactions. Blood examination showed a moderate increase of leucocytes. Pupils equal and reacted promptly. Diagnosed as latent labyrinthitis, chronic purulent otitis media, with mastoiditis.

A radical mastoid operation was done. The mastoid was pneumatic, containing many granulations. The antrum and tympanum were filled with detritus and pus. The sinus was exposed. All the semicircular canals were visible, but no fistula was found. The stapes was found loose in the opening of the oval window and was removed. There was no exposure of dura. All diseased bone was removed, the tympanum curetted, a flap made, and the incision sewed up.

Case III. J. S., twenty-two years old, was admitted to the hospital, December 19, 1915, with the symptoms of total deafness in the right ear, persistent nausea and vomiting, severe vertigo, and inability to stand without falling, coming on suddenly a few hours previously. The patient gave a history of a discharge from the right ear for the last ten years. On entering the hospital, temperature was 101° F., pulse 110. Examination of the right ear showed a canal filled with thick, foul smelling pus, with destruction of lower half of drum membrane, the upper portion with short process of malleus and part of hammer handle were intact. A polyp attached to the inner wall of the tympanum protruded into the canal. Mastoid region not sensitive. Blood count, 12,000 white, with eighty per cent. polynuclear. Smear showed a mixed infection. No Kernig or Babinski. The eye grounds were normal. Total deafness in the right ear, elicited by words and numbers spoken in loud voice, the function of the other ear being excluded by means of the Barany noise apparatus. Tuning forks not heard through the air. In the left ear there was slight impairment of hearing, with an intact and functioning labyrinth. Examination of the eyes showed a spontaneous rotary nystagmus to the left or sound side, the nystagmus being increased in intensity when the eyes were directed to the left, and diminished when turned in the opposite direction. Irrigation of the right ear with hot water had no effect on the nystagmus. The turning test failed to show an active right labyrinth. The fistula test gave a negative result, which was to be expected with a destroyed labyrinth and consequent loss of vestibular irritability, and did not rule out the presence of a fistula. Patient was unable to stand without help, and preferred to lie quietly in bed on the left side. On sitting up, he would fall to the right and complained of the objects about him rotating. The typical character of the symptoms pointed to an acute suppurative inflammation of the right labyrinth, involving all its component parts, cochlea, vestibule, and semicircular canals.

Under cocaine anesthesia, the polyp and a few granulations were removed from the middle ear, and frequent saline irrigations were ordered. December 16th, three days after admission, the temperature, pulse, and respiration were normal, the nausea and vomiting had ceased, the vertigo was slight, and the spontaneous rotary nystagmus was less marked. The Weber sign was lateralized to the left. The right ear was still deaf to tuning forks and voice, and showed no reaction after irrigation with hot water. December 20th, temperature, pulse, and respiration were normal. Vertigo was present only on sitting up, spontaneous nystagmus was present when the gaze was directed to the left, and very slight when the patient looked to the right. There was a profuse discharge from the right ear. On December 27th, there was slight rotary nystagmus only when the gaze was directed to the healthy side. There was vertigo on sitting up. With the exclusion test, the right ear showed profound deafness. On January 3rd, the patient was comfortable and out of bed. He showed some disturbance in equilibrium. On walking with the eyes closed, there was slight deviation and a tendency to fall to the right, and the patient experienced difficulty in turning around. Occasionally there was slight vertigo. There was rotary nystagmus only when the patient looked to the left. The vertigo was decidedly less. There was a slight disturbance in equilibrium. The temperature, pulse, and respiration were normal. The discharge from the right ear was moderate and less fetid in character. The patient was fairly comfortable; there was no spontaneous nystagmus, only occasional vertigo, and slight disturbance of equilibrium due to destruction of his right labyrinth and consequent defective orientation. There was total deafness of the right ear, and no caloric reaction after prolonged syringing. Discharge from the right ear was scant and nonfetid in character.

This case is of interest in showing the spread of an otitis media to the labyrinth without involvement of the mastoid and with complete destruction of the cochlea and vestibule, also the limitation of the disease to the labyrinth without involvement of the vital intracranial structures. The extension of the inflammation from the middle ear to the labyrinth may have been due to the impaction of the polyp in the perforation of the drum membrane, with the subsequent forcing back of the discharge into the inner ear through one of the various openings communicating with the oval or round window or through a necrotic area in the promontory or through a fistula of the external semicircular canal.

Case IV. Mrs. G., seventy years old, had discharge from both ears since childhood, with defective hearing, especially

in the right ear. Frequent attacks of pain on the right side of the head in the parietal and mastoid regions for past two weeks, pain in the ear and mastoid more marked. On admission to the hospital, October 10, 1915, temperature was 103° F.; the right external canal was filled with abundant pus, and there was absence of drum membrane. No ossicles seen. Posterior superior wall of external canal bulging. There was complete deafness on the right side and lack of response to hot and cold water. Swelling and tenderness over right mastoid. The left ear was filled with pus and drum membrane destroyed. Slight hearing present and vestibule reacted. Weber to the left. Tuning forks not heard in right ear through the air or bone. No compression or aspiration response. No ataxia. Spontaneous nystagmus absent. Diagnosis was latent labyrinthitis with mastoiditis secondary to otitis media purulenta chronica.

A radical operation was performed, disclosing extensive destruction of cells, the necrosis extending far forward into the zygoma beneath the posterior and middle fossæ and back behind and around the sinus with exposure of the soft sinus wall. No ossicles were found. The oval window was exposed and the margins were found filled with granulations. The facial nerve was seen exposed for a distance of one quarter of an inch below the external semicircular canal. There was twitching of the face when the tympanic cavity was scraped. The mastoid cavity and the middle ear were completely cleaned out, the granulations removed from the oval window and the wound was partly closed.

A few days after the operation there was severe headache, high temperature and slight stiffness of the neck; the symptoms indicating a possible meningitis. However, with Kernig not present and Babinski negative, normal patellar reflex, pupils equal in size and reacting to light and accommodation, and mentality normal, the diagnosis was uncertain.

On the fifth day an erysipelatous edema appeared on the right side of the face and relieved anxiety. The erysipelas spread over the entire face and then subsided. The temperature now dropped to normal and the remaining course of the convalescence was uneventful.

The cases presented are of interest as showing one of the dangers incident to a chronic discharging ear. The infection may reach the labyrinth by way of the oval or round window through a fistula of one of the semicircular canals or a fistula of the promontory. In the cases presented the suppuration, after destroying the labyrinth, had become localized and subsided into a latent stage. Repeated tests of hearing and reactions confirmed the diagnosis of latent suppurative labyrinthitis. Often a more serious outcome is the result of purulent labyrinthitis. With the numerous avenues of infection to the endocranium from the inner ear, cerebral or cerebellar abscess, meningitis, or thrombosis of the sinuses may complicate the condition. The labyrinth was not opened in any of these cases because there was no indication for the procedure. One of the cases enumerated was an acute purulent labyrinthitis with rapid destruction of function, but the temperature subsided within four days, and there was no evidence of spread of infection. Expectant treatment was therefore resorted to.

In the other cases the labyrinthitis at time of examination was of a chronic and latent nature secondary to a long standing otitis media with a complicating mastoiditis. Exenteration of the mastoid cells with curettement of the tympanum sufficed for the condition. Opening of the labyrinth, with no labyrinthogenous intracranial complication and no permanent symptoms of irritation of the labyrinth, such as nystagmus, vertigo, and disturbed orientation, would have been meddlesome and uncalled for.

221 Second Avenue.

THE EPILEPTIC SYNDROME AND GLANDULAR THERAPY.

Grand and Petit Mal Treated with Cessation of the Attacks,

By James L. Joughin, M. D., D. P. H.,
New York,
Instructor in Neurology, Post-Graduate Medical School and Hospital; Clinical Assistant, First Division, Neurological Institute.

The study of the normal and pathological physiology of the endocrine glands is at the present time assuming vast importance in the realm of medicine. The very obvious relation of these glands to metabolic disturbances and the profound influence which they undoubtedly exert over the entire human economy, is continuously becoming more and more impressed upon us. The clinical expressions translating their disordered function are slowly evolving, so that through the mist of uncertainty which today envelops us vague forms may be distinguished, which at some future time we hope to see materialize to reveal to us diagnostic and therapeutic possibilities of striking potency.

We are as yet far distant from this goal which we so ardently desire to reach, but we are decidedly progressing toward it. The recognition of the fact that a uniglandular symptomatology does not exist, that a pluriglandular symptomatology, dominated if you will by the preponderating disorganization of one or more glands, always exists, is a great step in the right direction. The intricate and little understood relations existing between all these structures is now everywhere recognized, and the cautious physician will certainly not dogmatize too positively as to the landmarks in this *terra incognita*.

Every contribution to this subject has at this time a decided value, especially if it is of the nature of clinical data or other objective phenomena observed by the physician. This variety of contribution will ultimately give to us a solid foundation of fact on which we may subsequently erect a satisfactory and stable superstructure to replace those rickety hypothetical fabrications which every individual investigator apparently deems it his duty incontinently to rear. The following case is reported as one of an epileptic syndrome associated with certain somatic findings considered to be indicative of pituitary disorder which presumably has been completely cured by glandular therapy.

Case. The patient, E. T., complaining of convulsions, presented herself at the dispensary of the Neurological Institute in May, 1914. At that time she was sixteen years old, a stout, well developed girl of more than average intelligence. Family history: Mother died at thirty-eight years from "spinal meningitis," father at fifty-four years from "cancer of the throat." There were three brothers older than the patient, two in good health, and one afflicted with Pott's disease. One sister younger than the patient was in normal health, another sister when eighteen years

old had two convulsive attacks at a two weeks' interval of unknown nature. According to the patient, after the first attack her sister was paralyzed on the left side, after the second attack death ensued within a few hours. I doubted, however, the accuracy of these statements, as her knowledge was not first hand. There was no other history of any nervous disease in the ascendants. Personal history: The account of her personal history and the evolution of her present illness were extremely interesting in detail Of her birth and early life it was impossible to speak with accuracy, as from the age of eight years she had been the inmate of an orphanage. She contracted measles before entering the institution, but there was no knowledge of her having suffered from any other disease incidental to childhood. In 1912 she experienced some febrile disturbance of considerable severity and prolonged duration, the nature of which could not be definitely determined. She had always been intellectually above par, winning medals for proficiency in her studies. Noteworthy was her decidedly sweet tooth, apparently more marked than usual in adolescent girls.

The first symptoms of the present illness occurred in January, 1913. At that time she began to suffer from severe paroxysmal headaches accompanied by vertigo and vomiting, usually bitemporal, but occasionally extending to the vertex. When asked to indicate where these headaches were situated, of her own volition she placed her index fingers on her temples. In February, 1913, one month later, menstruation first occurred, at which time she was fourteen years and eight months old. The flow was scanty, the duration one to two days, but it occurred at the physiological intervals during March, April, and May, and then abruptly ceased to reappear in October. From that time until she entered the institute, it was irregular.

In April and May, 1913, her hair, previously so abundant that she could not wear it up without a headache, began to fall out in large quantities, so that (so the patient stated) she lost fully two thirds of it. During this same eventful spring she became stouter and this continued throughout the year, so that on entering the hospital twelve months later her weight had increased from 100 to 150 pounds and she was still becoming heavier. With the development of this general adiposity, her hands became broader and plumper and the fingers "pointed." She noticed also that during the spring and summer of this year, drowsiness frequently overwhelmed her, she yawned a great deal, and volunteered the information that this sense of fatigue accompanied by a profound muscular asthenia ultimately forced her to abandon the physical setting up exercises which for years she had regularly performed at the convent.

By far the most interesting phenomenon of this period was the orderly development of a complete epileptic syndrome, which rapidly evolved through the stage of petit to that of grand mal. In February, 1913, coincident with the first menstruation, occurred an attack of momentary unconsciousness, "a dark spell" as she described it, which recurred at fairly frequent intervals. During these "spells" she would let fall scissors, spools and other objects which she held in her hand, and a few seconds later, on recovering consciousness, would find them where they had fallen. Being alone on several such occasions, she was astonished on recovering consciousness to find, standing alongside of her, one of the sisters, who had in the meantime entered the room. These "spells" evidently constituted the first of her petit mal attacks. About this same time she was told by the sister on night duty in the dormitory that she was acquiring a habit of grinding her teeth during sleep, and on more than one occasion she awoke in the morning with a bitten tongue, and at least once with a severe contusion of the head. She never fell in these earlier attacks, but later often did, bruising and cutting herself.

Convulsive attacks supervened with "twitching of the face, rolling of the eyes, and jerking of the limbs," and accompanied by loss of consciousness. Each month she had from two to four of these major attacks and numerous minor attacks. There has never been any sphincteric incontinence. In addition to these epileptiform seizures, she had several nocturnal fugues, the nature of which could not be determined accurately. In November, 1913, subsequent to a convulsion she went to bed at her usual retiring hour, 6.30 p. m., and knew no more until she awoke some time later and found herself in the barn of the institution. She had unbarred doors, etc., to get there, but had put no slippers on or otherwise clothed herself.

As previously stated, during February, March, April, and May, 1913, she menstruated scantily. In June, at a date approximating twenty-eight days after her last period, while alone in a room, sitting at a sewing machine, she felt her lower extremities becoming numb (sensory aura). This feeling, ascending, gradually diffused over the entire body, and she finally fell unconscious from her chair to the floor. There she was found, so she was later informed, with blood flowing from the nose, mouth, and eyes (subconjunctival hemorrhage?) and with her face twitching. She did not recover consciousness for many hours, and on so doing was amazed to find herself in bed, wearing a blood stained nightdress and with a nurse in attendance. This phenomenon, evidently one of vicarious menstruation plus an epileptoid seizure, recurred at successive menstrual epochs until October, 1913, when menstruation *per vaginam* recommenced and she experienced no such attack. The convulsions occurring at other times were also less frequent and less severe if she menstruated regularly. Owing to the severity and frequency of these attacks, the patient was obliged to abandon her project of becoming a sister in the institution. All these symptoms and incidents persisted with little change until she entered the hospital in May, 1914.[1]

Examination at the time of her entrance into the hospital showed nothing of interest from a strictly neurological standpoint. Her station, gait, and reflexes were all normal. There was no motor or sensory disturbance. The special senses, sphincters, and speech were unaffected. The pupils reacted promptly to light and accommodation, and the fields of vision were normal. Fundus findings were negative. All the cranial nerves were intact. The most noticeable thing about her was the generally distributed adiposity. Figure, *typus femininus*. The hair on the head was of normal distribution, very fine, fairly abundant, but easily pulled out. There was no pubic or axillary hair. The skin was dry and a little scaly. She perspired nocturnally. something she did not do previous to the occurrence of the febrile illness earlier referred to. Her hands were rather broad and plump, but with definitely tapering fingers. The crescents of the nails could be seen. On viewing the facial profile, there was possibly some maxillary prognathism. Her teeth were excellent, large, and not spaced. I have no record of her height at this time, but she was of average stature. Blood pressure systolic 105, diastolic 90. Pulse ranged between 64 and 90. Temperature normal. She entered the hospital and received while there a daily dose of about 250 grams of glucose without producing glycosuria. Any effort to increase this dose resulted in emesis. A nasopharyngeal examination was not made. The x ray showed no enlargement of the sella turcica, atrophy of the clinoid processes or absorption of the dorsum sellæ. Unfortunately we did not take radiographic plates of the hands, so we did not learn whether the epiphyseal lines were persistent or not.

CONCLUSIONS.

This patient I considered to be suffering from the effect of disordered pituitary function and I was led to this conclusion owing to the close analogy which hers presents to similar cases described by Cushing and classified by him under the caption "primary adolescent hypopituitarism." Strongly suggesting this diagnosis were the severe bitemporal headaches, the fineness of the hair and its marked tendency to fall out, the tapering fingers of the hypopituitary type of hand, the adiposity, the late development of the secondary sexual characteristics, and the increased carbohydrate tolerance. That epileptoid convulsions may occur in these cases and that

[1] In addition to these undoubtedly epileptoid seizures, the patient gives a history of an attack occurring the day she left the convent which is very strongly suggestive of hysteria. Her emotional stress on leaving the institution and taking up a new life may have accounted for this. The attack was witnessed by her aunt and was not of the same nature as the episodes already described.

administration of the gland thus apparently indicated, may benefit the patient, has been shown by Cushing.[2] I therefore instituted pituitary feeding with what I think may conservatively be called remarkable therapeutic results.

On leaving the hospital in May, 1914, she began to take daily doses of eight to ten grains of pituitary extract. Two weeks later she menstruated for the first time in three months and did so regularly during the months immediately subsequent. Her weight decreased within three months from 150 to 126 pounds, a loss of twenty-four pounds. Her temporal headaches almost immediately disappeared, her hair gradually ceased to fall out, and her general health rapidly improved. A very definite and marked benefit thus resulted from this glandular feeding, but the most striking indication of the efficacy of the treatment was manifest in the cessation of the petit and grand mal attacks. So far as I can ascertain, she has never had an attack of either variety since beginning this treatment, though of course there always remains the possibility that the petit mal may have occurred at times and passed off unobserved. This could have been, however, only very exceptionally or it would have been noted and reported by those in the patient's immediate environment. The major convulsive seizures have never recurred and she has remained free from all manifestations of epilepsy until this date (May, 1916), two years after the administration of the first dose of pituitary extract.

Treatment has been intermittent. The patient does not take medication when she feels well, and in this way two or three months will elapse without therapy. Sooner or later, however, the menstrual flow ceases, at which times "dizzy headaches" recur, "right where they always come," indicating the temples. She becomes sleepy and fatigued and excessively irritable and restless, whereupon I immediately resume treatment with invariably gratifying results. Of late I have combined with the pituitary a small dose (one half grain daily) of ovarian extract, and the response from the standpoint of the catamenia has been more satisfactory than when the former extract was administered alone.

Unfortunately the patient is decidedly temperamental. If she has a dispute with those with whom she is living she will refuse to take her tablet in order to vex them. If at any time she experiences what she considers sufficient improvement, she discontinues medication of her own volition. When she finds as a result that a few months later no menses appear, she does not report at once to the physician, but waits another month or two until she is so uncomfortable she is obliged to present herself for further investigation. Temperamentally unreliable, given to prevarication and falsification, I am unable to say whether these foibles are another expression of her infirmity or a result of the unfavorable environment of the large institution in which she passed her formative years. Possibly both factors are to be considered.

It may not be amiss, in closing, to emphasize that here we have a patient who should not be treated by bromides or other sedative medication. We are treating her not symptomatically, but by removing the etiological factor, something unfortunately we are not always able to do. Physiological deviations of the endocrine glands are coming more and more into prominence as causative factors in the production of the syndrome of epilepsy and the number of cases which we are thus able to treat satisfactorily is slowly increasing. Let us not, however, again commit an error as we did in the early days of bromide therapy and neglect the hygienic and dietetic management of the patient. Even in these days of organotherapy its importance as an adjuvant method of treatment can hardly be overestimated.

CHRONIC GONORRHEA.*

By William S. Barnes, M. D.,
New Haven, Conn.

In attempting to write a paper on this threadbare subject, I feel that we might be placing our time to better advantage by considering other more valuable subjects for discussion. Perhaps it may be worth while, however, to relate my experiences with this disease, thereby adding my mite to what has gone on before. I do not wish to adopt the usual textbook procedure, but rather discuss the disease from the practical standpoint of one who treats it as it comes to one after it has been under the care of others; by others I mean the druggist, confidential friends, who may or may not have been infected at some previous time, and the general practitioner.

The most prominent and distressing objective symptom of a case of chronic gonorrhea is the presence of a discharge at the meatus. The patient may or may not have many serious lesions in his genital organs (though of course he may be unaware of this), but what concerns him most is the evidence at his meatus of a discharge. If we will only stop this everlasting discharge, he will impress upon us the fact that we will have one more grateful patient.

Let us rule out at the outset the sexual neurasthenic. Many cases of gonorrhea reach this class. I believe, though, that if they did not have this disease to occupy their nervous minds, they would find equal solace in some other malady. Many of these cases are pitiful, and we can spot them readily after making a thorough examination of their symptoms. These cases should go to the neurologist.

It is my practice to take a thorough history of every patient. I find a comprehensive history blank very valuable. It helps us remember many important points that we should otherwise overlook. A perfunctory examination is never of much value; we should get as many facts as possible, in order to make a complete diagnosis.

In the consideration of a case of chronic gonorrhea, should there be present a urethral discharge, it is my practice to investigate this evidence of the disease. I examine a smear for the usual organism before any effort is made to proceed further. Many men regard the morning drop to be free from

*Read before the New Haven Medical Association, June 21, 1916.

gonococci, and therefore feel that they are justified in passing sounds or other instruments into the urethra with the hope of bringing about a cure. It has been my experience to find cases that have had all kinds of urethral treatment, even to the passing of the posterior urethroscope, show gonococci in the urethral discharge. I am firmly convinced that it is bad practice to pass sounds or other instruments into a urethra unless the discharge is free from gonococci. Should the passage of instruments cause the organisms to reappear in the discharge, we should immediately return to the treatment usually given in the acute condition. I wish to emphasize this point very strongly, as many cases have been brought to a serious condition by neglecting to keep a sharp lookout for gonococci. I find it possible for a chronic case to present acute symptoms, even though it has not been reinfected.

I have in mind a patient with chronic gonorrhea of three years' duration, referred to me by a physician in this city. I saw him shortly after he had left the physician's office, where he had had several sounds passed into his bladder. At the time I saw him he had his usual discharge; a smear showed many gonococci. I presume that the physician believed that because this patient had had a discharge for that number of years, and because he was without other symptoms, sounds would be an effective aid to a cure. Unfortunately for the patient, that had been the opinion of several other men who had seen him. It is needless to say this patient should have had other treatment.

After satisfying myself that the urethral discharge is free from gonococci, it is my practice to investigate the urethra in order to determine whether there is any narrowing of the urethral canal. I do this with the urethral bougie à boule, beginning with a very small size, gradually increasing until I pass the largest one that will enter the meatus. Any obstruction to the passage of these instruments is carefully noted, by measuring on the instrument the distance from the meatus. Very often, on withdrawal of the instrument, discharge is noted on its shoulder. A very small meatus would require a meatotomy in order to give this information. With the foregoing facts concerning the case, we are in a position to proceed.

As a general rule the patient is asked to empty his bladder into two glasses after a smear of the discharge has been taken. The bladder is then filled with a weak permanganate solution. This fulfills two purposes, one as a bulwark upon which to make pressure during the massage of the prostate and vesicles, secondly to wash out any material that may be expressed during the act. A thorough massage is made in accordance with the conditions affecting the case at that time. The secretion obtained from the discharge is very important: it is my practice always to look for gonococci in this expressed material. The material is also examined for different epithelial cells which are usually present. I have followed the teachings of Heitzman in this procedure, and I must say with considerable satisfaction. It is possible by this method to differentiate the cells that are given off during the massage. If we follow this method we should be able to note cells from the urethra, ejaculatory ducts, prostate, and seminal vesicles, should any be present. This observation should make it possible to tell where the sickness is, and predominance of any one of these cells would point to the organ principally involved.

Should the results of my examination point to disease in the urethra and with the idea of investigating disease in the posterior urethra, I proceed to examine the patient with the posterior endoscope. With this instrument we are able to see the verumontanum and the floor of the posterior urethra, also to apply treatment to this part of the urethra and along the anterior urethra. Most often a combination of endoscopic treatment and dilatation with the Kollman dilator will bring about favorable results in a large percentage of obstinate urethral affections due to gonorrhea. An interesting case which came under my care some time ago will illustrate many points regarding the treatment of chronic gonorrhea:

Case. Man, aged twenty-four years, clerk, single, German parentage. Family history good. Had contracted gonorrhea three years previously. At the time I saw him he had a urethral discharge with no gonococci. There was no pain; the discharge was yellow and white at different times. Patient had a double stream. His previous treatment had been injections. His meatus took a No. 29 bougie à boule. Obstruction was felt at the fossa navicularis and at the bulbous urethra. His first urine was hazy with long and small shreds. Second urine was hazy. The inguinal glands could not be felt; the scrotum was long and lax, testicles normal, epididymes normal, spermatic cords normal. Prepuce lax, in folds partly covering glans. Microscopic examination of discharge showed pus cells, urethral cells, and diplococci. Both vesicles were hard and enlarged. The prostate was soft and flabby, with areas of hard infiltration. The expressed material contained cells from the vesicles, ejaculatory ducts, prostate, also spermatozoa and a predominance of urethral cells. Posterior endoscopy showed the posterior urethra to contain areas of infiltration; the verumontanum was enlarged and also infiltrated; some areas of denuded mucous membrane were seen. The anterior urethra also had denuded areas, also many follicular enlargements. There was a thickened area at the bulbous urethra.

This patient had seventy-five treatments in about two years and a half. Sounds, the largest of which was No. 29 French, were passed sixteen times. Massage was performed twenty-eight times. The Kollman dilator was passed twenty-five times, going as high as No. 37. Anterior and posterior endoscopy was performed twelve times, using ten to twenty-five per cent. silver nitrate solution. Irrigations of one to 4.000 permanganate or silver solution always followed sounds, except in sixteen instances, when deep instillations of silver nitrate from one to five per cent. were made through the Bangs tunnel sound, size No. 18. This patient acquired a slight epididymitis one year and five months after treatment was instituted.

This patient shows a perfectly clear urethra by means of endoscopic examination. His first urine is clear and sparkling, but contains the very finest shreds. His second urine is clear and clean. There is absolutely no discharge. A complement fixation test gives a negative reaction. The patient is able to drink beer and other alcoholic beverages without ill effects on the urethra.

In conclusion, I will state that the treatment of chronic gonorrhea should be based on accurate diagnosis of the organs affected. The microscope and cultures of the discharge give valuable information. Proper instrumentation with application of counter-irritation by means of solutions of silver nitrate offer the most satisfactory means of bringing about a cure.

VERIFY YOUR REFERENCES.

A Word to Medical Writers,

By Frank Place, Jr.,
New York,
Assistant, Library of the New York Academy of Medicine.

Dean Burgon (1), in his life of Doctor Routh, tells the story from which I take my text. Mr. Burgon, then a recent graduate of Oxford, called one day upon the venerable president of Magdalen College, Doctor Routh. His account proceeds: "I believe it was then that I ventured to address him somewhat as follows: 'Mr. President, give me leave to ask you a question I have sometimes asked of aged persons, but never of any so aged or so learned as yourself.' He looked so kindly at me that I thought I might go on. 'Every studious man, in the course of a long and thoughtful life, has had occasion to experience the special value of some axiom or precept. Would you mind giving me the benefit of such a word of advice?' He bade me explain—evidently to gain time. I quoted an instance. He nodded and looked thoughtful. Presently he brightened up and said, 'I think, sir, since you care for the advice of an old man, sir, you will find it a very good practice (here he looked me archly in the face) *always to verify your references,* sir.' "

Verify your references. That is my text, and in the present instance I wish to direct this text particularly to the medical man who would venture into print. It is to be assumed that he has fulfilled Billings's (2) four rules for the preparation of a medical paper. 1. "Have something to say. 2. Say it. 3. Stop as soon as you have said it. 4. Give the paper a proper title." It is in the revision, the polishing off process, that he should, among other things, go over his list of references and verify them. To direct attention to this phase of authorship is the purpose for which this paper is written.

The science and art of medicine is so dependent upon its literature that reference to authorities is a recognized part of medical composition. The quantity of such printed matter is very great and quotation of sources is as necessary in medical literature as in any other field of literary endeavor. Such is the indifference on the part of writers, however, to the place and importance of the bibliographical reference that some attention should be directed to it.

What underlies that admonition, Verify your references, that makes it the only advice offered to a studious soul seeking help? It is of the spirit of the scientific method. Substantiate your statement by proof, either of your own or by the work that others have done before you. We work with the tools that others have made and placed in our hands, and we hope to make tools to place in the hands of others who follow us. If our predecessors have experimented and have left no record in material objects or written description, their works profit us nothing. For the purpose of storing up medical advance in deed and thought medical books and journals exist, and in them we shall find description of the processes of work that others have employed. To find these papers in the great mass of literature, indexes and catalogues were invented. In addition, most writers, in reporting their work or ideas, read and gather the publications that relate to their particular task; and then, to help others in the same line, to record their own research, and to have a line of defense against criticism, they print with their report a list of the papers they have consulted. Should not the scientist be as truthful and as accurate in recording his help as in giving his own work? One says "yes" without hesitation. How, then, can the author permit references to be printed which are not only false as to the fact, but which also seem to be intentionally so? Some so far forget science as to quote articles that it is plain they have never seen, but have lifted bodily from some other list. Certainly there should be some distinction between the article read and the one known only by hearsay. If an author would but put himself in the place of one of the audience whom he is addressing; if he would but read the paper and verify the references as if he had never heard of the subject before, then he would begin to realize some of the deficiencies of his paper and to appreciate the need for fullness and accuracy of statement in his bibliography; he would perceive the reasons for including data whose usefulness he had never before recognized.

It is hard to understand the point of view of the writer who is preparing a paper and who says: "No one will ever take the trouble to look up these references. They are near enough correct now. Let them look 'em up as I had to." The obvious reply is, "Why print your references at all then? If you are so little interested in your work as that, if you have so little purpose to help others, why do you even print your paper? There are plenty of papers waiting to be published that are just as good or better." The time an author spends in verifying his references is more than saved for every one of his readers. "Rong References" are frequently so very wild that it is hardly worth while to continue the search for them (3). The author, who knows the material, can more easily verify and correct his references before publication than any reader, "each in his separate sphere," can spend hours or days in finding them afterward. Nothing in science is too insignificant to notice. Therefore, verify your references.

The experience of writers and bibliographers has shown that the efficient bibliographical reference is the one containing the complete and correct answer to the questions, "Who wrote it?, What is it about?, When and where was it published?" Answering these questions the citation should stand as it does in the *Index Medicus* and in the *Index-Catalogue of the Library of the Surgeon-General's Office.* In referring to a book the details are these: 1. Author's name with initials. 2. Title of book. 3. Edition, other than the first. 4. Place, publisher and date (the imprint). 5. Volume, and page therein if a particular statement is to be quoted. On the other hand, a quotation from a classic, like Hippocrates, may be more readily accessible if the reference is to book, chapter, and paragraph. In the reference to a periodical article the details are nearly the same: 1. Author's name with initials. 2. Title of article. 3. Title of periodical. 4. Place and date of publication. 5. Volume, or series and volume. 6. Page, or inclusive paging. When space is not at a pre-

mium the unabbreviated form of words of titles is a desirable precaution against error. Printing the title of the journal in *italic* or UPPER CASE TYPE further serves to distinguish it from the title of the article. Some examples follow, each of which has a good list of references.

Harrower, H. R. The Hypophysis or Pituitary Body. In his Practical Hormone Therapy. London: Baillière, 1914. 287-319.

Janeway, T. C. Nephritic Hypertension. *Harvey Lectures, 1912-1913.* Phil., 1913. Ser. VIII, 208-251.

Cotton, F. J., and Boothby, W. M. Intratracheal Insufflation Anæsthesia. *Annals of Surgery.* Phil., 1913. LVII, 43-63.

In such stenographic material, unlike reading matter, both grammar and context, clues to the correctness thereof, are absent, and the necessity for careful revision is apparent. However much verification be done in the course of composition, and that may well be considerable, the bibliography should be gone over *in toto* in the proof. Really, the best way is to free one's self from the suggestion of copy, take the proof alone and consult the sources themselves, making the necessary corrections on the proof. Each detail of figure, letter, and mark of punctuation should be carefully scrutinized; spelling, date, volume number, page number, each should receive its own instant of attention. It is astonishing how many errors can be detected in a supposedly correct proof. Even then the influence of familiarity with the subject and with the articles consulted will slightly obscure the author's watchfulness. Some one unfamiliar with either will be more trustworthy in correcting the references.

"But why," some one asks, "is it not permissible, with all the catalogues and indexes we have, to say simply that Jones in 1900 did thus and so, or Jones, *Journal of Medicine,* 1900, said this and that?"

In the first instance, while you are saving space for yourself, you are probably wasting time for every reader of your article; in the second place, you are not saving enough to counterbalance its lack of efficiency; and in both cases the reference is of little worth in its collateral uses. In addition, you are mistaken in thinking that indexes are going to point out the article sought for at once, if at all. The indexes in magazines are themselves arguments for complete and correct reference. Indexes range all the way from the full and carefully made, like those in the *Journal of the American Medical Association* and the *Journal of Experimental Medicine,* through the slovenly and incomplete with elaborate but useless "table of contents," down to total absence of both "contents" and index. Atrophy and complete absence of index are too common in both journals and books; too common to speak well for medical journalism, and too common to trust medical literature to its mercy. The index may be lacking either from failure of the editors to have one made by a competent person, or from failure on their part to make the index an integral part of the magazine as published. Either cause is inexcusable and is decidedly bad for both journal and reader. These considerations lend emphasis to the demand for complete and correct references in bibliographies and to the slogan, Verify your references.

To the uninitiated all the details for a complete reference seem like redundance of information. To such the necessary points would be only the author, the journal, the year, the volume, and the page. In certain conditions, to save space, this brevity may be imposed upon one, but let it be only at command of the editor and when he brings forward proof of its necessity. For it must not be forgotten that the bibliography has uses beyond its connection with the article to which it is appended. A good bibliography is often used as a source of references without regard to the point of view of the paper itself. Frequently it is used by the student of the subject as a starting point for research rather than some of the more inclusive bibliographies like the *Index-Catalogue.* Such a list is also called upon to locate papers that other reference books do not include. The more thoroughly the work on the bibliography is done, the greater is the service that it performs. As a finishing touch to the paper then, verify your references.

Though I have elsewhere (4) in greater detail taken up reasons for the inclusion of the several data in a reference, I wish to list some of them briefly here.

The author's name identifies the workman. The bibliography is an author index of the material referred to; it helps in this way in finding articles that indexes have omitted or that are too recent for any other index.

The title identifies the paper itself, especially when the author has written much on the subject. The title defines the scope of the paper without further search.

The place of publication (and in the case of a book, the name of the publisher) is of aid in identifying the publication.

The date of a book, journal, pamphlet, or other printed thing is, next to name of the author, the most important fact in scientific bibliography. It establishes the worth of the work as to its timeliness and its position in questions of priority. The date is a point of departure for finding other articles, later or earlier; it furnishes a clue to the scope of the paper.

The volume number reduces the quest to a single book; in most cases to a single sequence of pages. This is no small item in the case of a journal that publishes several volumes a year. The *Biochemische Zeitschrift* issues almost an even dozen volumes during the twelve months.

The page number directs the reader immediately to the point sought; while inclusive paging gives him in advance an idea as to the length of the article. When given, the page reference obviates the use of the index, which may be absent, or useless, or omit the entry one seeks.

For one reason or another the searcher is sometimes unable to find the original article that he needs; all that is available is an abstract. Let him give a reference to the original as fully as possible from the information that he has, and then give also the citation of the abstract; something like this:

Murri, A., L'atassia nel cammino e nel nuoto. *Riforma medica.* Naples, Sept. 11, 1915, XXXI, No. 37. (Abstract in *Journal A. M. A.,* Chic., 1915, LXV, 1496.) From this it is seen that he has de-

rived his reference from the *Journal A. M. A.* while the original article is to be found, so far as he can say, in *Riforma medica.* This method has its uses in quoting papers in other languages than English and in giving other sources in order that at least one may be available to the reader.

Give the title of the journal from which you quote. This seems as self evident as an axiom, but it is not as foolish a request as it appears to be. This detail is omitted in references often enough to call for a few words. Instead of doing this simple thing, writers sometimes give only the name of the society before which the paper was read, an item of some meaning perhaps, but of little direct value in locating the paper. "Society of neurology," or *Société de neurologie,* does not suggest to every one to look in the *Revue neurologique* rather than another neurological magazine.

This leads me to another point. Give authorities as they are printed, not as you would like to have them printed. If the title is in French, give it in French. A seeker who cannot read French will not then spend time in digging up papers he cannot read. No one can object if, in addition to the title, a translation into English is given, especially if the other language is one that is generally unfamiliar, as Russian or Danish. In quoting other languages, however, great care must be exercised in transcribing names and titles of papers. To get the force of this take up a list of references in some foreign journal and observe those to English or American literature. Hilarity is likely to ensue. Parker Syms appears as Darker Syms; "Diseases of the Pituitary Gland, by E. G. Fearnsides, M. A., M. D., B. C. Cantab., . ." is given in a *Jahrbuch* as by "E. G. Feamsider & B. C. Cantch." Verification is vexation, but it is the price of safety.

A common fault lies in taking a reference from another's bibliography as though it were thereby Gospel truth itself. Faith may remove mountains, but in science ye are known by your works. "If the great Schmidt gives this reference, it is good enough for me." That is where trouble begins—or is continued; for the possibilities—nay, the probabilities—are that Professor Dr. Geh. Schmidt allowed an inexperienced assistant to round up the references; that another, equally untried, omitted to verify them in any way and in copying altered this one unconsciously; while a third let the printer still further maltreat it. The result, fair without but false within, may mean nothing even to Fetlock Jones or Doctor Swatson. Take no reference for granted. Verify the reference that your best friend gives you. Verify the reference that your revered chief gives you. Verify, most of all, the reference that you yourself found and jotted down. To err is human, to verify is necessary.

Unless references are verified from the originals, marvelous are the results that are sometimes attained. Articles that mean nothing are ascribed to mythical authors; journals are quoted that never will be published, and dates are indicated that none of us will ever live to see. A classic example of bibliographic cacogenics is shown in the descent of the reference to a report of a case of urticaria by J. V. Hjelmman, published in a Finnish journal in 1899. This was abstracted in *Progrès médical,* Paris, Jan. 27, 1900, 3. ser., XI, 60, but with no indication of its source in the Finnish journal. This French abstract was translated into English and printed in the *Medical Bulletin,* Phil., May, 1900, XXII, 175, but credited to "J. V. Hieleman, *Progrès médical*" and without date, volume, or page. This translation was transferred bodily to the *St. Louis Medical and Surgical Journal,* August, 1900, LXXIX, 96, credited to the same Hieleman, but now as originating in the *"Bull. Med. and Surg."* "J. C. J." transplanted this hardy annual to the October number, 1900, of the *Journal of Cutaneous and Genito-Urinary Diseases,* N. Y., 1900, XVIII, 470, again deriving it from *"Bull. Med. and Surg.,* 1900," but also giving due credit to the St. Louis journal. Probably from the *Journal of Cutaneous and G.-U. Diseases* as his authority Hans Hübner added "Hielemann, *Bull. Med. and Surg.,* 1900," to his bibliography which appeared with his article in the *Archiv für Dermatologie,* Wien, 1906, LXXXI, on page 219. Seeing one of these latter references, who would turn for the original to *Finska Läkaresällskapets Handlingar,* Helsingfors, 1899, XLI, 1236-1241? And echo answers, "Who-who."

Verifying references means work, sometimes a good deal of work; but if your article and bibliography are to be worth anything they should be worth the work to make them so. Why not have the best? If they are not worth the work, they are not worth printing. While the directions herein enumerated are many and seem to make a counsel of perfection, the fact that these ideas have been acted upon by some writers shows that they are feasible. And yet these arguments for correct and complete references are not all that might be adduced. Every day, it seems to me, some newcomer turns up which reveals a new outlook on the uses of the bibliography. In every case the correct reference becomes a time saver, a short cut through the hills of print. Wherefore I say again, Verify your references!

Primary Carcinoma of the Lungs.—Jonathan Forman (*Medical Record,* Sept. 9, 1916) shows from statistics that this condition is more frequent than is usually supposed. Adler was able to collect only 374 authentic cases from the literature up to 1912, therefore as 120 cases have been reported since that time it is apparent that earlier statistics were defective. The majority of the so called cases of primary carcinoma of the lungs are really of bronchial origin, while a casual microscopic examination may lead to a diagnosis of sarcoma in certain cases of lung carcinoma. Four cases are reported by Forman, all in males aged from forty-eight to sixty years in all of whom the lifetime diagnosis was that of tuberculosis and the true pathological condition discovered only at autopsy.

Our Readers' Monthly Prize Discussions

Twenty-Five Dollars Is Awarded for the Most Satisfactory Paper

All persons, whether subscribers or not, are invited to compete for the prize of $25 offered for the reply deemed best by the editors to the following questions:

CLXXIV.—How do you treat ivy poisoning? (*Closed.*)

CLXXV.—How do you treat furunculosis? (*Answers due not later than October 16th.*)

CLXXVI.—How do you treat Colles's fracture of the radius? (*Answers due not later than November 15th.*)

The award will be based solely on the value of the information contained in the answer. No importance will be attached to literary style. Answers should preferably contain not more than six hundred words, and should be written on one side of the paper only. All papers submitted become the property of the JOURNAL, and should bear the full name and address of the author for publication. The prize will not be awarded to the same person more than once within a year.

The prize of $25 for the best answer to Question CLXXIII has been awarded to Dr. A. W. Nelson, of Cincinnati, Ohio, whose paper appears below.

PRIZE QUESTION NO. CLXXIII.

THE TECHNIC OF CIRCUMCISION.

BY A. W. NELSON, M. D.,
Cincinnati.

The technic of circumcision depends upon the age of the patient and the anomaly to be corrected. For convenience the technic may be made to correspond with three periods of life, namely, 1, infancy; 2, childhood; 3, adolescence and adult age.

Preparation.—The parts to be operated on should be rendered sterile by washing, first with soap and water, and then with a solution of bichloride of mercury one in 4,000. If the preputial opening is too small to permit retraction of the prepuce, the preputial cavity should be irrigated with the antiseptic solution alone. Should the penis be affected with an infectious and autoinoculable disease, for instance, chancroid, impetigo contagiosa, etc., the operation should be postponed until the infection has disappeared. The same may be said of constitutional diseases in which any operation is contraindicated.

Next pass the penis through a small opening in a sterilized towel, which is then spread out, giving a sterile field to work in. Now examine carefully the conformation of the parts, to determine how much to remove. Retract the prepuce, if possible, to observe the size, shape, and relations of the frenum, etc., also notice whether the rhaphe runs directly in the median line. If the prepuce cannot be retracted, pass a fairly stout probe into the preputial cul-de-sac to see if there are adhesions; if they are present, we may attempt to break them up.

Operation.—The aim, whenever possible, is to operate under local anesthesia, to use few instruments and a simple form of dressing.

As a rule no anesthetic or sutures are required in young infants. Occasionally a catgut suture is applied at the frenum. The prepuce is grasped at the mucocutaneous junction, drawn forward, circumcision forceps applied in an oblique direction, following the oblique line of the glans, and the redundant prepuce is cut away with a sharp pair of scissors, preferably curved on the flat. The forceps is now removed and the skin allowed to slip back. With scissors the mucous membrane is slit down to the corona by means of a dorsal incision, and the flaps are trimmed away on each side, aiming to avoid the frenum, and leaving about a sixth of an inch of mucous membrane to approximate with the cutaneous layer.

If the frenum is cut and there is spurting from a bloodvessel, either catch the bleeding point in the suture or ligate it with catgut. The mucous layer is now turned backward to meet the cut edge of the skin, the parts are wiped and dressed with a five per cent. clean boric acid ointment and bandaged lightly.

If there are adhesions between the glans and prepuce, first try gently to separate them with a probe, and if not successful, after making the dorsal slit, partially or totally, separate the parts by stripping with pieces of gauze wound around the fingers. The raw parts are dressed freely with the boric acid ointment.

The dressings are changed about once in twenty-four hours, oftener if they are saturated with feces. Saturation with urine is no indication for change of dressings, which are continued until the wound has healed completely.

In childhood, patient and operating field are prepared as described above. The best results are obtained under general anesthesia. Nitrous oxide-oxygen, alone, or supplemented by ether, is excellent. Have a good anesthetist. We prefer usually the open operation, dorsal incision, and trimming of the flaps. With two pairs of hemostats the prepuce is grasped laterally, one on each side, and gently drawn forward, while a dorsal incision cutting through the mucous membrane and the skin at the same time is made with a Mayo scissors. The cut is made to about a quarter of an inch of the point where the mucous membrane is reflected on the glans. The prepuce now has the appearance of two dog's ears, which are trimmed off by following the oblique line of the glans, leaving about a quarter of an inch of flap. If possible, the frenum should always be left intact. If this cannot be done, there should be no hesitation—divide it and tie the bleeding vessels. Now see that the parts are symmetrical, the edges of the wound even, and that bleeding is controlled. The cut edges of the skin and mucous membrane are approximated so that the rhaphe and frenum are in distinct anatomical continuation, and interrupted sutures of catgut are introduced; the first suture at the frenum, the second in the middorsal region. The sutures should be

placed about a sixth of an inch from the margin of the cut edges, and should not be tied too tightly, so as to avoid inversion of the flaps, excessive swelling of the parts, unnecessary pain to the patient, and cutting through of the sutures.

Adhesions and other complications are handled in the same way. As a rule the dressings do not require to be changed as often as in young infants. Usually the older the child, the less frequent the change of dressings. In older boys it may be advisable to prescribe a mixture of potassium bromide and potassium nitrate to allay nervousness and prevent erections after the operation. The patient may be permitted to be up and about from twelve to twenty-four hours after the operation.

Adult and adolescent cases present the greatest possibility for variation in technic and anesthesia. Local anesthesia with 0.5 per cent. novocaine is preferred. General anesthesia is not often required, but when necessary nitrous oxide-oxygen, with or without a little ether, as the occasion may require. is excellent. The sterilization and preparation are as already described. A small piece of rubber tubing or a soft rubber catheter is tied around the shaft of the penis. If the prepuce can be retracted the anesthetic is injected into the skin in a circle at the proposed line of incision. The prepuce is next drawn back and the mucous membrane is infiltrated in a circle close to the corona. Where the prepuce cannot be retracted, the anesthetic is injected as follows: Place the rubber tubing around the shaft of the penis, near the root, and inject the novocaine into the body of the penis, in front of the band, by making four stabs with the needle, in a circle, each time depositing seven or eight drops of the anesthetic in a quarter of the penile circumference. Avoid puncturing the urethra. Now wait from five to ten minutes and proceed with the dorsal incision as described above. The rubber band should be removed before introducing the sutures, in order to see if there is free bleeding, also as a prophylactic measure against secondary hemorrhage, and as an aid to thorough approximation of the parts. The rest of the technic is the same as described in performing the operation under general anesthesia on children. In the adult silk sutures are preferable, and are to be removed from five to seven days after the operation. The parts are either dressed with the boric acid ointment or kept moist with boroglyceride, and bandaged. If possible, avoid erections by giving either a bromide mixture, or camphor monobromate in two grain doses. Usually patients are able to resume work within twenty-four hours of the operation.

Dr. Oswald Joerg, of Brooklyn-New York, writes:

In infants and boys up to about twelve years of age I try to avoid circumcision and, if necessary, I dilate the foreskin by pushing it back with my fingers and slipping it above the glans penis, at the same time loosening the adhesions existing between the two. Sometimes this procedure is difficult, but is made easier by causing an erection.

In preparing for the circumcision I wash the parts thoroughly with hot soapsuds and clean the preputial sac by injections of one in 2,000 solution of mercury cyanide. The penis is passed through a small opening made in the centre of a sterilized towel and the latter is spread out and fixed to the patient's clothing.

I use only local anesthesia by injecting with a hypodermic syringe a solution of novocaine *into,* not beneath the skin and mucous membrane at the place where the incisions have to be made, i. e., around the whole foreskin at the height of the sulcus and near the opening. I insert two drops at each puncture which I keep about one eighth inch distant. The solution consists of:

℞ Novocaini, ...grain ⅓;
Sodii chloridi, ...grains ii;
Solutionis adrenalini (1:1,000), ...mlviij;
Aquæ, ...ʒij.
M. Ft. solutio.

The injections cause a very light swelling, but never so much as to interfere with the operation.

Then I pull the foreskin forward more, if it is very long, less, if it is shorter, with the fingers of one hand or with a pair of forceps. With the other hand I apply a circumcision clamp obliquely parallel to the corona glandis between my fingers or the forceps and the glans penis, taking care that the latter is not caught. When I have an assistant I let him hold the penis and use gentle traction on the hinder part of the foreskin. With a very sharp scalpel I cut off the end of the prepuce which is in front of the clamp. If the hemorrhage does not stop of itself, I apply pressure with gauze dipped into the solution of mercury cyanide.

In most cases the outer membrane (the skin) retracts more than the inner layer (the mucosa). If possible I turn the latter up to adapt it to the former. Sometimes if the mucosa cannot be moved upward it is necessary to make one or two short incisions into it at the dorsum or near the frenulum with bistoury or scissors, or, if there are adhesions to the glans, to loosen them with a probe. If there should be any redundant mucous membrane near the preputial orifice, it has to be clipped away. When the prepuce is stripped off the glans, the coronal sulcus is often found covered with smegma.

There may be four bleeding points, a dorsal, two lateral, and a frenal. Any such artery is to be clamped or tied with fine catgut. If the bleeding is stopped I introduce as many silk sutures as necessary, sometimes only two, sometimes as many as five, about an eighth of an inch from the surface of incision. In some cases the adaptation is so good that no sutures are needed. As a dressing I use sterile gauze with the unguentum acidi borici U. S. Ph., and a small wound bandage, leaving free the orificium urethræ. The penis is held up by a sterile T bandage or a suspensory bandage to which a piece of cloth is fastened on both sides. The patient is allowed to go about.

The sutures are taken out about the fifth day and the bandage is removed after a week.

Dr. David Lazarus, of New York, observes:

The modus operandi depends upon the age of the patient and the condition requiring the operation. From a hygienic and sanitary viewpoint, every newborn male child should be circumcised, and the best method is cutting the foreskin with one movement

of the scalpel, first drawing the foreskin well forward, away from the head of the penis. In fact, the incision should be about one quarter to one half inch forward from the glans, thus not only avoiding injury, but also allowing for normal contraction of the tissues. Should the artery of the frenum be accidentally cut or bleed profusely it may be necessary to insert one stitch of No. 00 catgut—otherwise a simple sterile dressing is all that is required, as the parts usually heal in a few days.

Before proceeding with the operation, the foreskin should be drawn back well upon the glans penis, thoroughly cleansed, and all adhesions, if any exist, broken up and separated. Previous sterilization of the operator's hands and of the part to be operated upon, as well as strict attention to all rules of asepsis during and after the operation should be observed. Stitches, as a rule, are superfluous except for hemorrhage from the frenum artery; otherwise the little bleeding can well be controlled by a fairly snug dressing and bandage.

This operation can safely be performed without an anesthetic upon children less than two years old. In children above the age of two years a general anesthetic will be required and also the insertion of a few catgut stitches, so as to bring into good and close contact the skin and the mucous membrane; one stitch on the dorsum of the penis, one stitch on each side, and one, if necessary, at the site of the frenum artery. A simple dry sterile dressing, or one of sterile boric acid ointment applied snugly is all that is needed. No patients should be left unobserved for fear of hemorrhage.

In older children the operation for circumcision may be performed in the same manner as for adults, i. e., as follows: Circumcision becomes necessary for one of several reasons, e. g., cleanliness of the parts, adhesions of the prepuce, too long a foreskin, sores or wounds under the prepuce, chronic urethral discharges, and often partial treatment of hypertrophied prostates. The operation is best performed by a dorsal incision through the skin and mucous membrane carried close to the corona (but not too close, so as to allow for shrinkage and contraction) and then cutting away the foreskin with a circular incision by means of a curved scissors; in cutting the foreskin it is best to make the incision a little away from the frenum, so as to avoid the artery. After the foreskin is entirely removed, a few stitches are inserted, uniting and bringing in contact the skin and the mucous membrane, and should the frenum artery be cut by accident or otherwise, a stitch is put through to catch the artery and control hemorrhage.

In applying a dressing it is best to allow the stitches to be long, so that after being tied they will offer three quarters to one inch, so that after applying a small narrow strip of iodoform gauze and tying it upon the wound with the same stitch used for sewing we have a neat and small aseptic dressing. Above this small strip an ordinary sterile dressing is applied and the patient is permitted to go about, although it is best to rest in bed for twenty-four hours and to take a fluid diet with plenty of water, keeping the bowels in an active condition.

Catgut should be used, as it will be absorbed, and the wound need not be dressed for three or five days, when primary union will, as a rule, have taken place. The operation can be performed under a general anesthetic or under a local anesthetic of novocaine two to four per cent.

Dr. Hartford R. Burwell, of Washington, D. C., advises:

Antisepsis.—Cleanse part thoroughly with soap and water. Follow with bichloride one in 5,000. Protect with sterile towels.

Instruments.—Scalpel, one pair curved scissors, four artery clamps, one grooved director, needle holder (may use clamp to carry needle instead), one small cutting needle.

Suture material.—Black silk and No. 1 plain catgut.

Operation.—Outline circular incision one quarter inch behind coronal sulcus for entire circumference of penis. Place grooved director between prepuce and glans exactly in midline anteriorly. Cut through skin and mucous membrane with director as guide to circular incision outlined as suggested. Cut through midline posteriorly in same manner. Avoid artery of frenum. Cut off each lateral flap thus made with curved scissors, using outline first made as guide. Establish complete hemostasis by catching and tying bleeding vessels with catgut sutures. Complete operation by uniting cut edges of skin and mucous membrane with interrupted silk sutures (use catgut in young children) placed from one quarter to one half inch apart. Apply dry sterile dressing and bandage. Remove sutures in six to eight days.

Dr. Melville A. Hays, of New York, states:

The usual indication for circumcision is phimosis, but in older subjects it may be rendered necessary by the appearance of chancroids, etc., under the prepuce. The operation may ordinarily be done under local anesthesia (two to four per cent. cocaine solution), but in young or nervous children it is sometimes necessary to use a general anesthetic, either chloroform or ether.

The parts should be thoroughly cleansed with green soap and warm water followed by dilute alcohol, care being used to prevent abrasion of the skin or mucous membrane. A fairly firm constriction of the penis should then be made and the cocaine solution (when this is used) injected along the line of the intended incision. The prepuce is then drawn well forward and grasped in a pair of forceps long enough to project beyond both sides of the prepuce and so placed as to avoid injury to the frenum or its artery.

The projecting portion of the prepuce is now cut away by means of a sharp bistoury or scalpel, the upper edge of the forceps being used as a guide for the incision. The forceps are now removed and the skin permitted to retract, exposing the mucous membrane; the mucous membrane is now trimmed off with the scissors, a margin of one sixteenth to one eighth of an inch being left all around. If the artery of the frenum has been cut, it must now be ligated with fine catgut, while all other bleeding points are checked. The edges of the skin and mu-

cous membrane are now carefully brought together by a number of interrupted sutures (the number depending upon the size of the organ operated upon), horse hair and a very fine needle, curved or half curved, being used for this purpose.

The wound is now sponged carefully, dusted with finely powdered boric acid, and a strip of dry sterile gauze firmly applied; a piece of oiled silk, perforated to permit the protrusion of a portion of the glans with the meatus, is then applied and retained by a firm narrow bandage. In older persons, who will use care in urinating and be careful to dry the meatus with a pledget of cotton each time, this dressing may be left in place for four or five days; in younger persons it is usually necessary to change the dressing at least once and often twice in twenty-four hours. After removal of the stitches, the parts are dressed with powdered boric acid and a narrow gauze bandage.

The formation of "dogs' ears" which often mar the result of the operation, will be avoided by cutting the skin carefully, going as close as possible to the frenum, and trimming the mucous membrane very carefully so that there is left only a sufficient margin to permit of suturing.

(*To be continued.*)

Contemporary Comment

Standardized Hospitals.—Early medical education in the United States began upon a high plane. The first four medical schools organized before the Revolution required all applicants for admission to have served first an apprenticeship with some practitioner of medicine and to demonstrate their proficiency in science and Latin. The students then took one year of theoretical teaching and anatomy, another year of clinical instruction and still another year of hospital work. At the end of this time they received the degree of Bachelor of Medicine. After three years of practical work they returned to defend before the faculty an original thesis on some medical subject. If successful they received the degree of Doctor of Medicine. These were the European standards of that day. How these high standards were cut down in the early years of our national life by the mass of unschooled medical practitioners in an interesting story, but too long here to relate, observes the *Texas State Journal of Medicine* for September, 1916. From this colonial stubble a new medical profession is springing to life. Scientific and linguistic preliminary education have been reestablished; theoretical and clinical teaching have been strengthened in our medical schools and now come six medical colleges, Rush, Northwestern, Leland Stanford and the Universities of California, Minnesota and Vermont, requiring all applicants hereafter to pursue a year of hospital study, in an "approved hospital" before receiving a medical degree. The boards of medical registration of Pennsylvania, New Jersey, and Rhode Island have adopted this requirement for all future medical licentiates. It is probable that within five years this will be the uniform standard of all medical schools and State boards.

But where are these "approved hospitals?" The Council on Medical Education, after its arduous struggle for medical college efficiency, is about to begin the survey of hospitals in the United States. The American College of Surgeons will cooperate with a gift of $30,000 from the Carnegie Foundation for this purpose. Three years will be required to turn the searchlight on hospitals. Disclosures as to inefficiency will doubtless rival the startling shortcomings recently found in many medical schools.

We urge every member of the Texas medical profession who is connected with any hospital to ask "Is it well organized? Has it necessary funds? Has it adequate equipment? Does it give safe service? Has it a good follow up system? Has it a skillful, scientific staff? Is the training school efficient, etc.?" The last few years have shown a rapid increase in hospital construction throughout Texas. Hospital standardization will bring about a tremendous improvement, especially in our public and municipal hospitals, by establishing ideals and requirements of efficiency, below which no public institution will be content to operate and less than which the public will not accept. Every one of our hospitals should keep in touch with this movements and work toward the adoption of such plans as will insure its inclusion in the forthcoming list of Recognized and Approved Hospitals of the United States.

Kerosene in Throat Affections.—The *Medical Summary* for September, 1916, after discussing the immense number of new drugs forced upon the practitioner's attention, recalls how often we are obliged to resort to old remedies. It then proceeds to summarize from the *British Medical Journal* an experience of Dr. T. M. Clayton with kerosene.

Four grave cases of laryngeal diphtheria in young children ranging in ages from two to four years were treated by the internal administration of kerosene or "lamp" oil and recovery was attributed to the remedy. Two of the four cases were in such condition that tracheotomy was out of the question. It was not performed in any of these cases. All were treated by injection with antidiphtheria serum. To each, doses of thirty minims of kerosene oil were given thrice successively every four hours, then ten minim doses three or four times daily, until normal breathing was established, which occurred in all four cases in forty-eight hours. From the first dose breathing became easier, improving with each successive administration until it became tranquil. In no case was any untoward action of the petroleum observed. The author is inclined to give the chief credit of the four recoveries to the petroleum. Similar cases previously treated with antitoxin without petroleum had been lost. Two of the patients were practically *in extremis* when first treated with paraffin. The author is convinced that if petroleum were administered in the conditions variously diagnosed as spasmodic croup, membranous croup, or laryngeal diphtheria, many lives would be saved. The taste of the kerosene was disguised by means of compound decoction of sarsaparilla.

NEW YORK, SATURDAY, OCTOBER 7, 1916.

WORK OF THE STATE DEPARTMENT OF HEALTH.

On pages 50 to 55 of Governor Whitman's report to the voters of the State of New York for 1915, 1916, will be found matter of special interest to phycians; it is embodied in the letter to the Governor of Dr. Hermann M. Biggs, commissioner of health. The commissioner maintains that his prophecy of some years ago, that with a little support from the Governor and the Legislature, in five years 25,000 lives could be saved to the State outside of the city of New York, has been fulfilled. The death rate for 1915 was the lowest in the history of the State, and notwithstanding an increase of nearly 300.000 in population there were 2,000 fewer deaths than in 1910 from the communicable diseases. The courageous support of the Governor resulted in substantial concessions by the Legislature, and a new and properly equipped laboratory building in Albany will soon replace the shabby lean-to, made over from a stable, formerly used by the health department.

An emergency fund provided by the Governor was of incalculable assistance in the fight against the unforeseen epidemic of infantile paralysis which began last July; sanitary supervisors, nurses, diagnosticians, and bacteriologists in sufficient number have been appointed and necessary branches opened at Roslyn and Middletown. "An eminent surgeon" is being interviewed in the hope that he can organize clinics throughout the State for the purpose of instructing the general practitioner how best to prevent deformity from following the disease. A corps of skilled nurses will also be employed for the benefit of needy families.

A trained nurse has traveled throughout the State with exhibits, charts, diagrams, etc., to demonstrate how the enormous death toll of children may be reduced, how milk and drinking water should be handled, and how communicable diseases should be fought; the result in diminishing infant mortality has been most encouraging. More and more the village population is adding to its knowledge of sanitary matters with notable results to the general welfare. The department has beeen enabled to enforce the Vital Statistics Law, and has coordinated advantageously with the Department of Education in school hygiene, and in other matters with the Department of Agriculture, the Hospital Commission, the Prison Commission, etc. With the Department of Agriculture there has been active cooperation in the examination of foods, the detection of anthrax, and the distribution of information at the county fairs concerning sanitary matters.

To Camp Whitman the department was able to send a sufficient amount of typhoid vaccine, a water analyst engineer to secure a supply of safe drinking water, and a bacteriologist who examined not only the water, but the men engaged in the preparation of food in order to detect typhoid carriers.

Commissioner Biggs congratulates the Governor on the epoch making transfer of quarantine from State to Federal control; a transfer which has been energetically supported for many years by the NEW YORK MEDICAL JOURNAL. Among other advantages this relieved the State health board of a constantly increasing expense. The burden and responsibility of quarantine are undoubtedly matters for Federal control; since 1892 the physicians of New York have been fighting for this righteous change, fully aware of the indecent way in which the quarantine station was subjected to petty local politics. The number of immigrants coming into the port of New York, observes the commissioner, far exceeds that coming into all other ports together; and it was only proper that all the States should contribute rather than place the burden of expense wholly on the State of New York.

THE HASTY DIAGNOSIS OF PULMONARY TUBERCULOSIS.

The problem of the early diagnosis of pulmonary tuberculosis is one upon which volumes have been written, and the general practitioner has received much criticism for his failure to diagnose the disease early enough to assure a permanent cure of the foci already present. We need not enlarge upon the great need to make such early diagnoses, nor upon the benefits to be derived. We are all agreed upon this fundamental point in the effort to eradicate tuberculosis. The next step is to diagnose the early cases, as demanded.

All in all, the diagnosis of pulmonary tuberculosis in an early stage is not easy, even for the expert in this field. Many cases are so puzzling in the early stages, that, when confronted with them, even the expert finds himself in a state of indecision. What, then, shall we expect of the average physician, who has given but a moderate amount of time and energy to the problem, or, perhaps, has had no special training in this field?

One of the dangers in the effort to diagnose pulmonary tuberculosis as early as possible, is that cases of a nontuberculous nature may be labeled tuberculosis, with all that it means for the future welfare of the patient. Imagine diagnosing pulmonary tuberculosis in a patient who is really free from the disease in an active form, and his subsequent treatment as if he were afflicted with tuberculosis! Only one who has had the disease and made the sacrifices necessary to effect its early arrest can appreciate the full import of the wrongful diagnosis. This is perhaps especially true of a professional man who goes forth "to take the cure" in some far away resort or sanatorium, where he has no income, while his expense is by no means small; it may mean financial ruin. Financial ruin alone would not be so bad a result, if worse were not in store for a proportion of these persons. In some of them develop psychoneurotic states. Others become forever fearful of their health, and, in order to avoid possible overexpenditure of energy, limit their work so that they are never as fit and efficient as they were before. Still others become parasites upon their family, friends, or society. In fact one in whom tuberculosis has been wrongly diagnosed is apt to have as many types of reaction as one who really has the disease. Furthermore, if the patient has some other disease which requires treatment of some sort beside the general hygienic, dietetic, rest and fresh air treatment of tuberculosis, this too is neglected. The harm done may be irreparable.

Therefore, in spite of all that may be said in criticism of the practitioner if he fails to diagnose pulmonary tuberculosis at an early stage when the evidence is sufficiently plain, he should not permit himself to label any case tuberculosis unless there is positive evidence that tuberculosis exists, and that this tuberculosis is active and not inactive, since inactive or old, healed tuberculosis should not lead to immediate treatment. Is not the modern view well expressed in the saying, *Jedermann hat am Ende ein bischen Tuberculose?* (Everyone has tuberculosis once in his life.)

When we are uncertain as to the diagnosis, we should be frank enough to admit our uncertainty. This means that we should keep all doubtful cases under observation long enough to permit thorough study. If, after a careful observation by all possible methods, including clinical history, temperature, physical examination, sputum examination, x ray examination, and other methods of choice, we are unable to state positively that the patient before us has active pulmonary tuberculosis, we have no right so to label it. We can continue to keep the patient under observation, and, in the meantime, do all that is possible to improve his general health, regulate his habits, especially his hours of sleep, his hours of work, and his diet, with the addition of whatever individual hygienic measures we can employ.

Beware the hasty diagnosis of pulmonary tuberculosis. It is an obligation that we owe our patients, society, and our own consciences.

SKULL SURGERY.

Brain surgery is one of the latest developments in the art of wielding the knife, and it seems no slight undertaking, even in the twentieth century, to chisel through the cranial bones and to delve beneath the wrappings of the seat of consciousness; yet if brain surgery is new, surgery of the skull is certainly an exceedingly ancient practice.

Recent archeological explorations in Peru have brought to light, among other interesting remains, human skulls with as many as three large openings, circular, as if cut with a modern trephine. They were made during the life of the owner of the skull, for, in some cases at least, they show evidence that the healing process went forward in the edges of the bone wound. In Europe the remains of Neolithic man, dating back at least 6,000 years, show that the contemporary surgeon was exceedingly bold in exposing the brain. One of the skulls of this time has two large oval openings, one on either side, with evidence of Nature's repair of the edges of the wound. Moreover, these openings were made, not with a nicely adjusted steel centre pin trephine, nor even with the help of a metal chisel, but with slivers of flint.

It was supposed at one time that the holes in the skulls found in these ancient remains were punctured after death in order to set free the spirit of the owner, but the evidence of the inflammatory processes which followed the operation have changed that idea. It is not likely that the medicine man could have had any such post mortem intention, for it was not until comparatively recent times that the brain was considered to be the seat of the soul. It is as much this theory, in its religious connection, together with the forbidding thickness of the skull, that has made modern man consider the opening of the brain case so serious a matter, and to look upon the brain itself as an exceedingly delicate structure.

Why these early craniotomies were done, we can, as yet, only guess. Possibly severe headaches may have been a sufficient cause to bring consent to such strenuous measures for relief, though it would not seem that such afflictions were frequent in that early time. There is no evidence that the openings were made to relieve pressure on the brain after an injury to the skull, though such injuries must have been common in an age when weapons of war were sticks and stones. It may have been that the surgical openings were made at the site of such skull wounds as were followed by unconsciousness, the surgeon reasoning that the unconsciousness was somehow connected with the injury. Surely so callous a creature as our distant ancestor must have been, would not, if conscious, consent to have his skull sawed open with a flint chip or any other instrument. Did these distant ancestors of ours possess some anesthetic which served in these cases?

Modern exploration of the brain has shown that the organ is not so delicate and unapproachable as was once supposed, and that it can be delved into with the assurance of comparatively complete recovery. In many ways it is a simpler matter to open the dura than the peritoneum, but the former procedure, because the brain is the seat of mental activity, will always seem the more serious undertaking. No matter, however, what ideas the ancient medicine man had regarding the functions of the brain, he has set us a bold example of what may be done with little science and imperfect instruments. Considering the fate which often overtakes the unsuccessful healer of a primitive tribe, he was not only bold but brave.

RECURRENT POLIOMYELITIS.

Not long ago the statement was made by one of our most eminent authorities that "infantile paralysis is one of the infectious diseases in which insusceptibility is conferred by one attack." It seems to be pretty well established that as a general rule this statement is true; that an attack of poliomyelitis confers a lasting immunity in the great majority of cases. That this dogmatic statement, however, may not be invariably true is proved by a case reported by E. W. Taylor (*Journal of Nervous and Mental Diseases,* September). A child, three years old, had an attack of poliomyelitis in which the right leg and the left arm were chiefly affected. The paralysis of the arm passed away quickly, that of the leg improved in some measure, but remained evident. Three years later the child suffered from another attack, which set in like the first and rendered him extensively paralyzed, so that he could make few voluntary movements. In one week improvement began, especially in the left arm and right leg, the extremities which were mainly affected before. The left leg was rendered practically useless. Taylor says: "The onset with fever, followed by a flaccid atrophic paralysis, without sensory involvement and resulting in permanent muscular atrophies, are entirely characteristic and could hardly be due to any other cause. It does not seem open to dispute that there were in this case two distinct attacks separated by a period of three years of health."

A few other cases of apparent reinfection have been reported from time to time. Excluding all that seem to be in any way doubtful, as well as those in which the interval was four months or less, as it is quite possible that these were cases of exacerbation or relapse rather than of actual second attack. Taylor has collated from the literature four cases beside his own in which the interval was one of years. In these the intervals were two years and three months, six years, fourteen years, and sixteen years. The writers who reported the first believed their patient to have been a carrier, and that the harbored virus resumed activity at the end of a little over two years, an assumption that was not proved. Perhaps it cannot be disproved in any case, but it seems to be a more rational theory that recurrence after the lapse of fourteen or sixteen years is due to reinfection. However this may be, these cases make it clear that recurrent attacks of poliomyelitis have been known to occur, and we are justified in the conclusion that in rare cases an attack of poliomyelitis does not confer such an immunity that a second, independent seizure is impossible. This is true of the immunity conferred by all of the other infectious diseases with which we are acquainted, as it is imperfect in a greater or smaller proportion of the cases, so it is not astonishing that the immunity conferred by this disease should be imperfect occasionally. Still, such an imperfection appears to be infrequent and recurrent poliomyelitis to be rare.

LAMBLIA INFECTION IN UNTRAVELED ENGLISHMEN.

A. Malins Smith and J. R. Matthews write to the *British Medical Journal* for September 16th, of three men, two soldiers and a sailor, who came under their care and in whom Lamblia cysts were found in fair number. Only one of the men had ever been out of England and his absence had amounted to only two days spent in Holland.

The interest of these cases lies in the fact that almost certainly the infection of Lamblia was contracted in England. As to the probable date and circumstances of the infection, and as to the possible or probably connection of the Lamblia infection with the attacks of diarrhea the writers make no observations, for on these points the facts at their disposal afford no evidence. It is almost impossible now, and will shortly become quite impossible to offer any evidence as to whether Lamblia is indigenous in England. The presence of the numerous cases of returned soldiers carrying Lamblia will make it impossible to state whether any future case is of native origin.

THREADWORMS SIMULATING APPENDICITIS.

S. G. Papadopoulos, M. B., of London, communicates to the *Lancet* for September 16th the details of a case diagnosticated as appendicitis but which turned out to be one of ordinary threadworms. The patient, a girl aged twelve years, was admitted to hospital on July 1st with the following history: She was quite well up to two days previous to admission, when she woke up in the night with severe abdominal pain and vomiting. These signs continued to be very severe the following day. She vomited bile stained fluid continually and was unable to keep anything down. The pain was localized to the right iliac region. A private practitioner diagnosed acute appendicitis. On admission the temperature was 103° F., the pulse 128, the respirations 22. The patient had taken oil on the previous night and the bowels were opened once on the following morning. On palpation a definite swelling was felt about an inch above and on the outer side of McBurney's point. At the moment a retrocecal appendicitis with rupture of an appendix abscess was suspected.

The operation was a right rectus incision, disclosing normal intestines, gallbladder, kidneys, and ovaries. The mucous coat of the appendix, however, was slightly injected and the whole canal was full of colonies of actively moving threadworms. The girl left the hospital, quite well, fourteen days later.

The Illinois State Hospitals' Medical Association announces that its next meeting will be held at the Peoria State Hospital, Peoria, Ill., October 26th and 27th.

Meetings of Medical Societies to Be Held in Philadelphia during the Coming Week.—Monday, October 9th, Samaritan Hospital Medical Society; Tuesday, October 10th, Pediatric Society; Wednesday, October 11th, Philadelphia County Medical Society; Thursday, October 12th, Pathological Society.

A Gastrointestinal Clinic at the Northwestern General Hospital, Philadelphia.—A clinic for the diagnosis of diseases of the stomach and intestines has been established at the Northwestern Hospital, Philadelphia, which will be in charge of Dr. Louis Winfield Kohn, formerly assistant in the Johns Hopkins Hospital, Baltimore. Dr. J. Douglass Blackwood will have charge of the laboratory.

Management of Poliomyelitis.—Dr. Robert W. Lovett, professor of orthopedic surgery at the Harvard Medical School, read a paper on the Management of Poliomyelitis with a View to Minimizing the Ultimate Disability, at a stated meeting of the New York Academy of Medicine, Thursday evening, October 5th. The subject was discussed by Dr. Simon Flexner, Dr. E. C. Rosenow, Dr. Frederick Tilney, Dr. Charlton Wallace, Dr. G. R. Pisek, Dr. Foster Kennedy, and others.

Health Insurance in the Prevention of Tuberculosis.—Nearly 1,500 antituberculosis associations in almost every part of the United States will be asked to participate in a campaign for health insurance legislation by the American Association of Labor Legislation, according to an announcement of the National Association for the Study and Prevention of Tuberculosis. Bills asking for health insurance legislation will be introduced in more than twenty States during the coming fall and winter and the support of the antituberculosis associations and other public health organizations will be urged for these bills.

The Army Medical School will open October 16th, with the largest class in its existence. Up to date sixty-six students have advised the medical department of their intention to attend. Applicants for appointment in the Medical Corps of the Army who qualified at the examination held September 5, 1916, are: Dr. James E. Ash, Harvard Medical School; Dr. Luther T. Buchanan, Jr., Oxford, N. C.; Dr. Joseph M. Greer, Fort Huachuca, Arizona; Dr. Henry L. Krafft, Peoria, Ill.; Dr. Louis J. Regan, State Hospital, Utica, N. Y.; Dr. James F. Rochan, New Brighton, N. Y.; Dr. Cyrus B. Wood, armory, Louisville, Ky.

Medical Society of the Missouri Valley.—Dr. C. R. Woodson of St. Joseph, Mo., was elected president of this society, at the annual meeting held in Omaha, Thursday and Friday, September 21st and 22d, and other officers were elected as follows: Dr. E. W. Rowe, of Lincoln, Neb., first vice-president; Dr. C. B. Higginlooper, of Winterset, Iowa, second vice-president; Dr. O. C. Gebhart, of St. Joseph, Mo., reelected treasurer; Dr. Charles Wood Fassett, of St. Joseph, reelected secretary. A merger of the Medical Society of the Missouri Valley with the Tristate Medical Society of Illinois, Iowa, and Missouri was proposed and a committee was appointed to take up the matter with the officers of the Tristate body. Next year's meeting will be held in Keokuk, Iowa.

New York and New England Association of Railway Surgeons.—The twenty-sixth annual meeting of this association will be held in New York, October 18th and 19th, with headquarters at the Hotel McAlpin. Wednesday, October 18th, will be devoted to the reading and discussion of scientific papers, with an executive session and the election of officers. On Thursday clinics will be held in the leading hospitals of New York. Dr. William S. Bainbridge will deliver the address in surgery. Dr. D. H. Lake, of Kingston, Pa., is president of the association, Dr. H. G. Stetson, of Greenfield, Mass., first vice-president, Dr. W. H. Hodge, of Niagara Falls, second vice-president, Dr. J. K. Stockwell, of Oswego, N. Y., treasurer. Dr. George Chaffee, of Little Meadows, Pa., corresponding secretary, and Dr. J. H. Reid, of Troy, N. Y., recording secretary.

The Pediatrist and the Poliomyelitis Epidemic.—At a meeting of the section in pediatrics of the New York Academy of Medicine, to be held Thursday, October 12th, the evening will be devoted to a consideration of the lessons to the pediatrist from the recent epidemic of poliomyelitis. Papers will be read as follows: Epidemiology and Public Health Problems, by Dr. C. H. Lavinder, of the United States Public Health Service; Review of the Symptoms of Onset Collated from the Cases of Poliomyelitis at the Willard Parker Hospital, by Dr. May G. Wilson; Personal Experience of the Abortive and Meningitis Types of Poliomyelitis, by Dr. Leon Louria; The Diagnosis from the Point of View of the Laboratory Field Worker, by Dr. Josephine B. Neal; Treatment, Prophylactic and Curative, by Dr. Herman Schwarz; Problem of the Aftercare, by Dr. Donald Baxter. A general discussion will follow. The fall clinical meeting of the section in pediatrics of the Medical Society of the State of New York takes place on the same date, and the members have been invited to hold a joint meeting with the pediatric section of the academy. Dr. Royal S. Haynes is chairman of the section and Dr. Herbert R. Wilcox secretary.

Gifts and Bequests to Philadelphia Hospitals.—Announcement is made of the following legacies and gifts to hospitals in Philadelphia: The Samaritan, $100,000 from the late Charles W. Kolb; Episcopal, $1,000 from the late William H. Whitall and $10,000 from the late Hall Engles, who gave the same sum each to the Pennsylvania, the Presbyterian, the Polyclinic, the Jefferson; and the Samaritan hospitals and $5,000 each to the Jewish and the Medico-Chirurgical hospitals and the Home for Incurables; the Misericordia, the St. Agnes, and the St. Joseph's hospitals, $500 each from the late Annie McNulty; Howard Hospital, $2,000 from the late C. Cresson Wister; St. Mary's Hospital, $5,000 from George W. Nevil (second donation) and about $700 from the late Dennis Whalen; Presbyterian and Rush hospitals, $5,000 each, and St. Christopher's of Philadelphia and Children's of Atlantic City, N. J., $2,500 each from the late Eugene L. Sauter; Children's Homeopathic and St. Luke's, $2,000 each, by the late Rachael L. Jones; St. Christopher's, $5,000, by the late Theresa Scott; Home for Incurables, $1,000, and the Methodist Hospital, $500, by the late Mary S. Geiger; Presbyterian Hospital, a contingent bequest of $24,000 by the late David M. Barrick; St. Vincent's Maternity Hospital, $5,000, and St. Joseph's and St. Agnes hospitals, $1,000 each, by the late Mrs. Caroline Earle White.

Personal.—Dr. John Chalmers Da Costa has been appointed successor to the late Dr. William J. White as consulting surgeon to the Philadelphia General Hospital.

Dr. John B. Macdonald's appointment as successor to Dr. George M. Kline as superintendent of the State Hospital at Danvers, Mass., has been confirmed.

Dr. Frank Maltaner, of Leland Stanford University, Dr. W. E. Evans, of Knoxville, Tenn., and Dr. John Alexander McIntosh, Jr., of Raymond, Miss., have been added to the faculty of the College of Medicine, University of Tennessee.

Dr. W. C. Lyle has resigned as manager of the University Hospital, Augusta, Ga.

Dr. William C. Gorgas, surgeon general, United States Army, arrived in New York on September 25th after a two months' study of sanitary conditions in Chile, Peru, Bolivia, Ecuador, and Panama, as chairman of the yellow fever commission of the Rockefeller Foundation.

Dr. J. Lewis Ziegler, of Philadelphia, has been elected a member of the board of trustees of Bucknell University, Lewisburg, Pa.

Dr. Edward A. Treacy has been appointed assistant gynecologist to St. Joseph's Hospital, Philadelphia.

Dr. Edward K. Tullidge, of Philadelphia, now a lieutenant surgeon, is with the Pennsylvania troops on the Mexican border.

Dr. James R. Clemens has been elected dean of the John A. Creighton Medical College, Omaha, Neb.

Dr. A. I. Ringer, formerly assistant professor of physiological chemistry at the University of Pennsylvania, has been appointed professor of clinical medicine (diseases of metabolism) at Fordham University School of Medicine, New York.

The Accuracy of Certified Causes of Deaths.—The committee appointed by the section in vital statistics of the American Public Health Association to consider the accuracy of certified causes of death and their relation to mortality statistics and the International List of Causes of Death, has submitted a report which appears in the September 22d issue of *Public Health Reports*. The committee is composed of the following members: Dr. Haven Emerson, health commissioner of New York city, chairman; Dr. William H. Guilfoy, Dr. E. H. Lewinski-Corwin, Dr. Louis I. Dublin, Dr. Charles Norris, Dr. T. Warfield Longcope, Dr. W. R. Williams, and Mr. George H. Van Buren, executive secretary.

Pertussis Vaccine.—The Health Department's whooping cough clinic, at Sixteenth Street and Avenue C, was discontinued on September 30th. This clinic was established more than two years ago for the purpose of gathering data on the therapeutic value of a specific vaccine for whooping cough, and the results achieved will be published in full in the *Bulletin* of the Health Department. Physicians wishing to use the health department's pertussis vaccine may obtain it, gratis (on condition they make a full report of their cases to the department), by applying in person at the Health Department Research Laboratory, foot of East Sixteenth Street, between the hours of 9 a. m. and 4 p. m., or on presentation by a messenger of a written request for the same signed by the physician. Printed directions for use are given out with the vaccine.

Tuberculosis Conferences.—Five sectional conferences on tuberculosis will be held in various parts of the country during the month of October. The first of the series, the Mississippi Valley Conference, met at Louisville, Ky., October 4th, 5th, and 6th, and the other conferences will be held as follows: New England Conference, at New Haven, Conn., October 12th and 13th; the conference for the Southwestern States, at Albuquerque, N. M., on the same dates; the North Atlantic Conference, at Newark, N. J., October 20th and 21st, and the last of the series, the Southern Conference, at Jackson, Miss., on October 30th and 31st. There is no membership nor registration fee in connection with these conferences, and any one interested in the tuberculosis campaign or other phase of the public health movement is invited to attend. Complete programs of the conferences may be obtained from the National Association for the Study and Prevention of Tuberculosis, 105 East Twenty-second Street, New York.

American Medical Editors' Association.—The program which has been arranged for the annual meeting of this association, to be held at the McAlpin Hotel, New York, on Wednesday and Thursday, October 25th and 26th, contains the following papers: Latin and Greek as Requisites to the Study of Medicine, by Dr. Abraham Jacobi; Responsibilities of Medical Journalism, by Dr. G. M. Piersol, of Philadelphia; The Special Journal versus the General Medical Journal, by Dr. William Benham Snow; Book Reviews in Medical Journals, by Dr. H. Sheridan Baketel; The Relationship Between Medical Journals of the Day, by Dr. W. E. Jones; The Medical Journal and the Materia Medica, by Dr. Francis E. Stewart, of Philadelphia; The Private Journal and Its Sphere in Medical Journalism, by Dr. A. S. Burdick; Independence in Medical Journalism, by Dr. Llewellyn Eliot; Some Suggestions as to the Details of Medical Journalism, by Dr. A. L. Benedict, of Buffalo; two papers, whose titles will be announced later, by Dr. Ira S. Wile and Dr. George W. Kosmak. There will be a symposium on the duty of the medical editor in acquainting the doctor with medical legislation and its administration, and in giving his aid, cooperation, and support in the framing and enforcing of proper laws, with special reference to antinarcotic legislation. The papers and discussions in this symposium will be presented by prominent judges, physicians, and lawyers. The officers of the association are: Dr. Edward C. Register, of Charlotte, N. C., president; Dr. W. A. Jones, first vice-president; Dr. G. M. Piersol, second vice-president; Dr. Joseph McDonald, Jr., secretary and treasurer, 92 William Street, New York. Executive committee, Dr. C. F. Taylor, Dr. John MacEvitt, Dr. A. S. Burdick, and Dr. Joseph MacDonald, Jr.

Modern Treatment and Preventive Medicine

A Compendium of Therapeutics and Prophylaxis, Original and Adapted

THE THERAPEUTICS OF A PHARMACOLOGIST.

By A. D. Bush, M. D.,
Professor of Pharmacology and Therapeutics, University of Southern California.

Thirty-ninth Communication.

BRONCHITIS.

Those who have read the preceding article on acute catarrhal affections of the nose and throat will have found much of further applicability in the treatment of bronchitis. Inflammations of the trachea and bronchi are frequently but secondary extensions from mucous involvements of the upper respiratory tract; but whether the attack is primary or secondary there is a marked similarity of tissue reaction and of drug medication. In tracheobronchitis there is the characteristic active congestion of the mucosa, followed by excessive exudation, and a more or less prompt restoration to the normal. Unless vital resistance is at an unusually low ebb, convalescence proceeds in a definite manner little modified by medication, drugs being used solely to secure some alleviation of sundry more or less annoying symptoms. Obviously, if supportive or restorative needs arise, more energetic measures are demanded.

The attractive possibility of actual accomplishment makes attempts at aborting bronchitis ever alluring. Here again, thorough clearing of the *prima via* is a fundamental duty; possible toxins are thereby eradicated, the kidneys are temporarily relieved of some of their work, and another avenue of elimination becomes available. Sweating the patient utilizes the emunctory function of the skin, and, by the superficial hyperemia induced, tends to relieve the deeper congestions. Place the patient in bed, cover generously with blankets, put hot water bottles at his feet, have him imbibe copiously of innocuous hot drinks, and possibly give him a good Dover's powder. This treatment will tend to make the patient less uncomfortable eventually, even though it may fail to break the run of illness.

The use of belladonna is not so clearly indicated in bronchitis as in rhinitis, though it has undoubted effect in reducing the mucorrhea; moreover, it would be of considerable service were there present any undue tendency to spasm of the bronchial musculature. In robust patients the use of aconite is desirable in bringing back into reasonable control an acutely upset vasomotor mechanism; but great circumspection is necessary in selecting both dose and patient, and the reaction needs to be carefully watched.

If the cough becomes too harassing, if it interferes too much with the patient's hours of repose, some sedative may well be employed, and codeine is probably as satisfactory for this purpose as any obtunder of sensory reflexes, but its administration should not be continued one hour longer than is absolutely necessary.

Much has been written, but little demonstrated, concerning expectorant mixtures; and sundry drugs have been recommended because of an assumption that they liquefy the bronchial secretions. One of the early phenomena attending convalescence from bronchitis is increased fluidity and copiousness of the bronchial secretions; and it is not unlikely that some hasty generalizers have credited this phenomenon to the use of some medicine previously administered; but mere sequence is not a demonstration of causation, as our students are frequently warned, and convincing evidence is lacking that the bronchial secretion is stimulated by any drug known. A drug frequently recommended for this purpose is the chloride of ammonium; but sal ammoniac passes through the carnivorous animals unchanged, though altered to urea in the herbivorous animals; and Cushny says the pulmonary epithelium is impermeable to the ammonium ion; so it is a pharmacological puzzle how ammonia can be of any service in promoting bronchial secretion. But if it has utility, the best way of administering it is by means of deep inhalations of the nascent chloride vapor. This mode of treatment has been often recommended, but clinical reports as to its real efficiency are very scanty. Let us have many experiments with this vapor, and careful reports as to any real determinable value.

Certainly the room should have a relative humidity of at least fifty per cent. This may be partially attained by means of vessels of water kept constantly boiling, to which may be added experimentally menthol or oil of eucalyptus.

Antityphoid Vaccination in the Presence of Albuminuria.—Widal and Méry (*Presse médicale*, June 8, 1916) report a study of the effects of antityphoid vaccination in twenty-five military chauffeurs in active service, all with albuminuria and in twenty-six men admitted to hospitals either for albuminuria or for other persisting signs of renal involvement. The vaccine used was a heated preparation immunizing against both types of paratyphoid organisms as well as against the typhoid bacillus. Nearly all the men received four injections at weekly intervals. The observations showed, in the first place, that the vaccinal reactions are no more marked in albuminurics than in normal subjects, whatever the dose of vaccine given. In none was there a return of any of the functional evidences of Bright's disease, such as high blood pressure, edema, or uremic symptoms. The amount of albumin passed was in some instances unaffected, in others increased, and in still others slightly diminished after the vaccine injections. Often the effects of successive injections on the albumin in a given subject were different. Where the albuminuria was augmented, the increase generally began on the second day after the injec-

tion, and lasted often only a day, sometimes two or three days, rarely longer. Preexisting casts, leucocytes and erythrocytes sometimes showed a slight, but temporary increase after the injections, and at times one or more of these bodies appeared in urine previously free from them. The urea content of the blood and the Ambard coefficient showed insignificant and temporary oscillations after injections. On the whole, the vaccination was thus well borne not only by those free of all disorder other than albuminuria, but by subjects who had previously had symptoms of Bright's disease. While it is recognized that men who have recently had hematuria or acute nephritis, who pass more than one gram of albumin per liter of urine, or whose blood serum shows more than 0.5 gram of urea per liter, should be relieved of military duties, several of the albuminurics studied by the authors came under these specifications and yet showed no ill effect from antityphoid vaccination. Admission to military service thus, from the standpoint of albuminuria, certifies the subject's aptitude to vaccination. Albuminurics considered incapable of withstanding so mild a procedure as antityphoid vaccination should not be kept in the army, exposed to typhoid infection.

Intravenous Vaccine Therapy in Typhoid Fever.—Petzetakis at a meeting of the Société de biologie (*Presse médicale,* August 3, 1916), reported excellent results from intravenous administration of antityphoid vaccine in enteric fever. The injection is followed by a marked thermal reaction lasting from two to five hours. Within six hours after the injection the general condition is improved, headache, coma, the typhoid state, and the other symptoms of the disease being relieved. Pulse dicrotism disappears, and the arterial pressure rises, Meteorism is lessened, the appearance of the tongue is altered, the stools become regular and normal, and complications are prevented. Copious sweating and a drop in the temperature likewise follow the injection. A leucocytosis is induced, and the urinary output is increased for one or two days. Where no serious renal parenchymatous lesions exist, the renal filter is apparently not influenced by the procedure.

Serum Therapy in Typhoid Fever.—A. Rodet (*Bulletin de l'Académie de médecine,* August 8, 1916) reports results obtained in 400 cases with serum prepared under his direction. When the serum is administered early enough, it usually arrests the progress of the intoxication and shortens the disease. To act most efficaciously the serum must be begun before the eleventh day. Later the effects are inconstant and usually less pronounced. The initial dose is fifteen to twenty c. c., subsequent doses usually less and decreasing in size—ten c. c., five c. c. The injections are best given at two day intervals. Three injections usually suffice. At times the effect on the temperature curve is seen on the day after the initial injection; oftener, after thirty-six or forty-eight hours; occasionally, later still. In a rather large ratio of the cases the descent of temperature is rapid and regularly progressive, the normal temperature being reached in six to eight days; instances of such abortion of the disease may be observed in cases very severe at the outset. In other cases, defervescence is slower, with amplified diurnal oscillations; more rarely, usually in cases treated late, the temperature reascends after a temporary drop, the specific action of the remedy having given out. Other symptoms follow the temperature changes; those due to nervous intoxication show especial benefit. Often the improvement precedes defervescence, the first effect of the serum sometimes being a state of euphoria noticed within a few hours after the first injection. Recrudescences and relapses are not rare, but constitute no objection to the serum, betokening rather an incomplete or insufficiently prolonged specific action, probably remediable by better regulation of the doses or resumption of treatment. In 167 cases running a regular course and treated with serum before the eleventh day, the average duration of the disease was 23.7 days; in twenty-eight similar cases receiving serum only after the eleventh day, thirty-three days. Preexisting advanced tuberculous lesions or a simultaneous or secondary infection with streptococci, staphylococci, diphtheria bacilli, etc., interfere with the efficacy of the treatment. Indeed, where the serum seems devoid of action, a suspicion of some mixed infection is warranted. The serum is actually of diagnostic value, producing little or no effect even in such closely related disturbances as the paratyphoid fevers. Recently the writer has prepared an antiparatyphoid serum, to be used analogously.

Cholelithiasis.—R. Alexander Bates (*American Journal of Surgery,* September, 1916) summarizes the points to be observed in the treatment of cholelithiasis as follows: 1. Biliary concretions, for the most part are composed of cholesterin, which is a normal constituent of bile, a monoatomic alcohol easily broken up by again restoring bile to normal 2. Cholesterin precipitation occurs only in stagnated, decomposed bile. 3. The rhythmic contractions of the gallbladder musculature are probably due to its secretin, which is similar to the secretin of the duodenum. 4. Medication should aim to alkalinize the bile, stimulate the bile secreting and excreting mechanisms by activating biliary secretion, and aid biliary antisepsis and mucosa tone. 5. Necessary surgery is in no way to be deprecated.

Unilateral Symptomless Hematuria.—R. L. Payne, Jr., and William B. MacNider (*Jour. A. M. A.,* Sept. 23, 1916) have shown that in addition to the presence of calculi, neoplasms and tuberculosis in the renal pelvis, this condition is often due to an infection of the medullary and pyramidal portions of the kidney with thrombosis, congestion, varix formation and hemorrhage. The treatment may be either operative or nonoperative. The latter comprises the injection into the kidney pelvis of styptics or of epinephrine and the administration of horse or human serum or of whole blood and of autogenous vaccines where the infectious agent can be isolated. This form of treatment, however, has the great disadvantage of masking symptoms where neoplasm or tuberculosis is the cause. Operative measures are far more satisfactory in general, for the exact diagnosis of cause can then be made. In the infective form complete nephrotomy gives excellent results, probably by establishing an efficient collateral circulation. In some cases, however, even of the infective form, cure can be assured only by nephrectomy.

Pyorrhœa alveolaris: Its Complications and Its Treatment with Emetine.—E. W. Koch (*Indianapolis Medical Journal,* September, 1916) says that although emetine hydrochloride is of benefit in the treatment of amebic pyorrhœa alveolaris, it alone will not cure the disease. Local dental treatment likewise, unaided and unrepeated, cannot produce a lasting cure. A rational management of this disease requires the employment of both measures, the emetine hydrochloride to remove the exciting cause, and the proper dental instrumentation to remove the predisposing causes and the factors that interfere with tissue healing.

Vaccines in Dental Infections.—Ernest E. Irons (*Jour. A. M. A.,* Sept. 16, 1916) considers that while active immunization through the use of vaccines has proved of great value prophylactically, the question of the value of vaccines in the presence of an existing infection is debatable. The administration of a vaccine in the presence of infection may quite as readily turn the balance against as in favor of the host, and it is nearly, if not quite impossible to foresee which will be the case. In cases of dental abscess a vaccine could at best be only an adjunct to other methods of treatment, and even as such it has proved disappointing. Further, proper dental surgical measures, with adequate drainage have rendered the administration of vaccines superfluous since cases do as well without their addition as with it. The same statements can be made with equal truth regarding the treatment of pyorrhea.

Ionization in the Treatment of Adherent Scar Tissue, with or without Contracture of Extremities.—M. Chiray and G. Bourguignon (*Presse médicale,* August 3, 1916) report excellent results from potassium iodide ionization in long standing scars which have become attached to subjacent tissues. The beneficial effects appear in a constant order, the scar first becoming pale, then thin and smooth, and finally loosened from the underlying tissues, over which it now glides freely. Tenderness of the scar completely disappears. In a series of 223 cases the treatment caused attenuation and complete loosening of the scar in eighty-five per cent. of instances; in the remaining fifteen per cent., loosening had not yet occurred when the man had to be discharged, but probably would have followed in some cases if the treatment had been kept up. The liberation of the scar occasionally takes place within eight or ten days, in the majority in five or six weeks, and in obstinate cases in three or four months. It is best to continue the treatment for some time after apparently sufficient results have been attained. In cases in which, after loosening of the scar, a deep fibrous scar is felt beneath it, ionization fails to influence the latter scar; these cases are subject to x ray treatment. The ionization frees any muscular or nervous tissue previously included in the superficial scar, thus improving motion and arresting local nerve irritation. Where the scarring has led to an established, though primarily "reflex" or "hysterical" contracture of the affected limb, forced mobilization by the surgeon himself is added to the ion treatment; in many cases improvement is rapid and in a few weeks free motion is regained. The gradual mechanical stretching is practised daily after the ionization treatment, being discontinued temporarily if sharp pains appear in the extremity. Anesthesia, forced correction, and fixation in a plaster cast were found practically useless. Excision of the scar is to be resorted to only if ionization and the x rays fail, as the vicious scars not infrequently recur after excision, though not after ionization. In the latter treatment the electrodes used consist of plates of zinc or tin of size corresponding to the scar and covered with felt or chamois skin. The negative electrode, moistened with one per cent. potassium iodide solution, is placed over the scar, and the positive, moistened with water, on the opposite aspect of the limb. A ten m. a. current is sufficient, yielding a more regular ionization than stronger ones. The current should not exceed 0.5 to one m. a. per square m. of electrode. The iodine ion is forced through the affected tissues with the current. Daily treatments each lasting one half hour are administered.

Treatment of Wounds by Ozone.—John Jeffrey (*Brit. Med. Jour.,* Aug. 26, 1916) states that septic wounds can be treated by the application of nascent ozone, including sepsis in such blind cavities as the nasal accessory sinuses. Usually after a very few applications the sepsis will have entirely cleared up and healing will begin in a healthy layer of tissue. The ozone can be readily prepared by passing a stream of oxygen from an ordinary cylinder through a small glass ozonizer and may be blown directly over the surface of the infected area by means of a Eustachian catheter, which can be inserted into every recess of the cavity.

Use of Picric Acid in Surgery.—T. F. Brown (*Lancet,* Sept. 2, 1916) reports that this substance is four times as active as phenol and is capable of destroying streptococci or staphylococci in two minutes in a one per cent. solution. On the strength of these facts the author has employed it as a wound dressing in war with the utmost success. He has developed the following routine as the result of an experience in over 3,000 cases. In superficial wounds a one per cent. solution of the acid was applied upon a thin layer of gauze, thus leaving the wound practically exposed to the open air. The dressing seldom had to be changed oftener than once a day. Deep suppurating wounds were syringed out twice daily with a one half to a one per cent. solution and mechanically cleaned every two or three days with peroxide of hydrogen. The same treatment was employed where there were sinuses. In the cases of suppurating fractures or extensively crushed tissues arm or leg baths in 0.5 per cent. solutions were given for half an hour at a time. After granulation in any case had reached the surface of the surrounding tissues, the solution used was never stronger than 0.5 per cent. since the stronger solutions seemed to damage the tender growing epithelium. In his wide experience the author encountered no contraindications and never saw a case of poisoning. The sole disadvantage of the drug was the deep and quite lasting staining of the superficial tissues. The drug was found to give good results in erysipelas in addition to open wounds.

The Mechanism of Saline Dressings.—Kenneth Taylor (*Brit. Med. Jour.*, Sept. 2, 1916) takes issue with Wright and proceeds to show many objections to Wright's statements and many fallacies in his arguments. He shows that hypertonic saline does not cause the pouring out of normal protective substances, that its action is essentially dependent upon the laws of osmosis, that its presence inhibits or checks tryptic digestion, and that it causes very marked cellular edema in the lining of the wound. Much the same objections apply to both isotonic and hypotonic saliines. He also points out that clinical experiences have not decisively proved the superiority of the saline dressings and that their theoretical indications are based upon an erroneous hypothesis of the structure of the tissues lining wounds. Certain of the actions of the hypertonic saline solutions are undesirable and even harmful.

Sarcoma of Intraabdominal Testis.—W. W. Grant (*Jour. A. M. A.*, Sept. 23, 1916) observes that this insidious malignant growth is seldom recognized early enough in its development to permit radical removal, but the experience of the author in a case of advanced growth indicates a hopeful plan of treatment. When the patient was first seen the tumor was too far advanced for surgical removal and the patient was put upon repeated injections of Colby's fluid. Under this treatment the tumor diminished in size and grew firmer. Remissions in treatment were followed by accessions of growth, so the treatment was continued for many months and a few x ray exposures were given. The tumor was thus checked in growth and reduced in size and encapsulation took place so that an operation succeeded in effecting its complete enucleation. This was followed by a course of x ray treatment and Coley's toxins. It is now over a year and a half since operation, and the patient remains free from recurrence and is apparently cured.

Action and Clinical Uses of Papaverine.—D. I. Macht (*Archives of Internal Medicine*, June, 1916) reports results of investigations of this opium alkaloid in both animals and man, including clinical cases. The alkaloid, generally used as papaverine hydrochloride or sulphate, was found to cause, by direct action on the heart muscle or its intrinsic ganglia, a marked increase in the tonicity of the heart, with slight slowing of the rate and an increased output. The drug is a powerful dilator of the coronary artery, and lowers general blood pressure, chiefly by directly dilating the bloodvessels, especially the splanchnic and peripheral vessels. While producing a slight narcotic effect, papaverine distinctly stimulates respiration, and is a bronchodilator. It relaxes all smooth muscle tissue, including strips of intestine, uterus, and bladder, and the excised pyloric sphincter. It also possesses general analgesic properties, forty mgm. of it being in this respect almost equivalent to ten mgms. of morphine, though the general narcotic effect is much less. The drug is of relatively low toxicity. Subcutaneous doses of forty to eighty mgms. in adults are quite safe. The author's clinical trials of the drug proved encouraging. In relieving pain it proved more effective than codeine, though inferior to morphine. In most instances of cardiac dyspnea it proved efficient. In an advanced consumptive habituated to herome, it relieved a troublesome cough, and in a case of aneurysm strikingly relieved cough which had not been influenced by any other drug. A case of bronchial asthma was relieved immediately. Its salient property of relaxing smooth muscle was also manifest in cases of spasm of the biliary ducts, and in pylorospasm, in which it was given by mouth with favorable results. It was also introduced directly into the ureter through a cystoscope in two cases of ureteral calculus, with successful effects. The peculiar effect of papaverine on the circulation, promoting coronary circulation and stimulating the heart while lowering the blood pressure, suggests its use in angina pectoris and cases of hypertension. Pal has used it to abort uremic crises. Its stimulating action of the respiratory centre suggests its use instead of morphine, where depression of that centre is undesirable. Macht slowly injected forty mgms. of papaverine, diluted with 200 c. c. of saline solution, intravenously on three occasions without any untoward symptoms.

Some General Information Concerning the Diagnosis and Treatment of Syphilis.—M. A. Reasoner (*Military Surgeon*, September, 1916) concludes thus with respect to the diagnosis and treatment of syphilis: 1. Syphilis should be diagnosed and treatment begun at the earliest possible moment. The dark field, or in the absence of this, staining methods, should be employed as an aid to diagnosis. The organism will not ordinarily be found for several days after the application of antiseptics, especially mercurial salts. 2. The interpretation of the Wassermann reaction is sometimes a matter of difficulty. In the absence of history or manifestations, a single positive reaction is not sufficient evidence upon which to base a diagnosis. In the presence of suspicious manifestations, indeed, several negative Wassermann reactions are not sufficient to establish a diagnosis. Other procedures may be necessary to confirm the diagnosis. Even with a uniform technic, the reaction of an individual may be subject to unaccountable variation. 3. The greatest good will be accomplished by the administration of both salvarsan and mercury. The best results are to be expected when treatment is begun early. The administration of mercury should be pushed to the physiological limit. The soluble salts of mercury have some points of superiority over the insoluble salts. Treatment by way of mouth does not give the best results. The results obtained from inunctions, when properly given, compare favorably with those from any other form of mercurial administration. Potassium iodide is not in itself an antisyphilitic drug. Its greatest field of usefulness is in the presence of tertiary gummatous lesions in conjunction with antisyphilitic drugs. Frequent examinations of the urine are desirable, as both salvarsan and mercury may exert an untoward effect upon the kidneys. 4. It is believed that syphilis is curable in a certain percentage of cases. A tentative standard has been proposed. Further investigation is desirable along these lines. 5 The results obtained from spinal fluid examina-

tions are of great value. These examinations should be more generally practised than is now customary. 6. The provocative Wassermann reaction is a refinement of the ordinary reaction. Information may be obtained from this reaction which can be gained in no other manner. 7. Rubber gloves are a desirable protection to the operator in handling syphilitics. 8. The luetin reaction has its greatest value in the diagnosis of hereditary and tertiary syphilis, tabes, paresis, and old cases of cerebrospinal syphilis. 9. In positive cases further information may often be obtained from a titration of the Wassermann reaction.

Laxatives in Abdominal Surgery.—Winslow Anderson (*Pacific Medical Journal,* September, 1916) lays stress on the avoidance of such drugs as aloes, cascara, jalap, etc., in abdominal surgery and pelvic inflammation. Three types of laxatives only are allowable in these cases, viz., salines, blue mass, or calomel in small doses, and castor oil. Where laxative enemas are employed, no soaps should ever be used, as they are too irritating and may set up inflammation not only of the rectum but also of the pelvic peritoneum or viscera. Suitable laxative enemas are:

1. One pint of normal saline solution at 102° F.

2. Two ounces of magnesium sulphate in one pint of water at 102° F.

3. Two ounces of glycerin in one pint of water at 102° F.

4. Two ounces of castor oil in gum arabic emulsion (one half ounce of acacia to one pint of water).

5. One half ounce of turpentine in one pint of gum arabic emulsion.

6.

℞ Fellis bovis, ...gr. xx;
Glycerini, ...℥i;
Aquæ amyli, ...Oi.
M. Fiat enema.

7.

℞ Infusi sennæ compositi, ...℥viii;
Aquæ, ...q. s. ad Oi.
M. Fiat enema.

8.

℞ Emulsi asafœtidæ, ...℥viii;
Tragacanthæ pulveris, ...℥ss;
Aquæ, ...q. s. ad Oi.
M. Fiat emulsum.

Prevention of Subinvolution and Retroversion.—A. C. Beck (*American Journal of Obstetrics,* July, 1916) states that in spite of careful trial of various measures recommended of late for the prevention of uterine abnormalities after the puerperium, including bed exercises, the knee chest position, repair of all lacerations, etc., the subsequent history of maternity cases at the Long Island College Hospital has shown these procedures to be inefficient, many cases returning with subinvoluted uteri and twenty to thirty per cent. showing retroversion. In the belief that having the patients walk on all fours might have a beneficial effect, this procedure was finally tried in a series of thirty-seven cases. On the ninth day after labor each patient was required to walk five or six yards on her hands and feet with the knees held as stiffly as possible. Next day the distance was doubled and the exercise carried out both morning and afternoon. The walk was augmented proportionally each day until discharge, the patient being then advised to continue until she returned two or three weeks later to the post partum clinic. The exercise was to be performed in the morning before dressing and at night after undressing. Whereas, among sixty patients in whom the procedure was not carried out, forty-five per cent. acquired retroversions, with subinvolution not infrequent and the vaginal discharge sometimes containing blood, among the thirty-seven who carried out the treatment and continued it at home, only 13.5 per cent. showed retroversion on their return and none showed subinvolution, the uterus being, in fact, in most instances considerably smaller than was to be expected at the time of examination. The condition of the perineum was observed to have little bearing on subsequent retroversion. Most of the trouble seemed to be due to neglect of patients after the second week post partum.

Acute Tonsillitis Complicated by Endocarditis.—W. D. Hoskins (*Indianapolis Medical Journal,* September, 1916) says that acute tonsillitis in children is not infrequently complicated by acute endocarditis, with resulting permanent injury. Children with acute tonsillitis should be put to bed and kept in bed until the fever has entirely subsided and all evidence of acute tonsillar infection has disappeared. When endocarditis occurs, keeping the child in bed and absolutely quiet for a considerable time will usually result in complete recovery. If acute tonsillitis in children was regarded as a serious disease, or at least as having serious possibilities, and was treated accordingly, some lives would be saved, and many children would be spared a life of chronic invalidism.

The Local Treatment of Burns.—R. J. Willan (*Brit. Med. Jour.,* Sept. 2, 1916) has worked out the following highly satisfactory plan of treatment on a series of twenty-eight cases of burns. The most essential single measure was the prevention of sepsis, which was found to be very fatal in burned persons. This was accomplished by the strictest observance of antiseptic precautions. The first step was the puncture and drainage of all blisters after sponging the surface with a five per cent. solution of phenol. The first dressing was one of a solution of picric acid, which was left on for two days if there was no infection. The occurrence of sepsis was looked for twice daily by smelling the dressings, which was found to be a valuable means of detection. In the absence of sepsis the picric dressing was removed after two days, the new blisters, if any, punctured, the wound covered with a mixture of equal parts of boric ointment, and petrolatum over which surgeons' lint was spread, and the whole enclosed in an ample dressing. In the presence of sepsis the wound was treated every four hours by hot boric acid fomentations under jaconet, all loose skin cut away and a dressing applied of alembroth wool, containing a small amount of bichloride of mercury. When the wound was rendered healthy the dressings were changed to those already described for nonseptic cases. A very simple form of first dressings for burns of the extremities was devised in the form of a single antiseptic wool covering which was held in place without pressure by means of a series of tapes.

Miscellany from Home and Foreign Journals

The Diagnostic Value of Tubercle of the Choroid.—Sydney Stephenson (*Lancet*, September 9, 1916) illustrates the great value of the discovery of tubercle in the choroid in the diagnosis of obscure cases by reporting three cases of general acute tuberculosis in which other diagnoses were made, and in which the correct one was possible only after the examination of the eye grounds. All three cases occurred in children, but tubercle of the choroid is not less common in adults where there is a general acute miliary tuberculosis. The reason for the general belief that choroidal tubercle is a rare finding lies in the fact that the eye is not usually included in the routine examinations made by physicians. If such were the case, tubercle of the choroid would often be found. The ophthalmoscope should be employed as a routine aid to diagnosis on the same plane as the stethoscope on account of the large amount of definite information which it yields.

Value of Recent Laboratory Tests in Nephritis.—Arthur F. Chace and Victor C. Myers (*Jour. A. M. A.*, September 23, 1916) state that extensive study of several of the newer tests of renal function has shown: 1. That an increase of uric acid in the blood is a valuable early diagnostic sign of beginning nephritis. 2. The blood urea is a valuable guide in treatment in moderately severe nephritis, since its changes reflect the patient's condition promptly. 3. Blood creatinin is of great prognostic value, indicating a fatal outcome in a comparatively short time if there is over five mgm. per 100 mils of blood. 4. Van Slyke's method of measuring the carbon dioxide combining power of the plasma is valuable as an index in both diagnosis and treatment. 5. In diabetes complicated with nephritis, determinations of the glycosuria are of little value, since the kidney permeability is lowered by nephritis. The blood sugar should be estimated in addition to that in the urine. 6. Finally, Ambard's coefficient has proved disappointing.

Observations in One Hundred Appendicectomies.—F. C. Warnshius (*Lancet-Clinic*, Sept. 9, 1916) noticed that patients with gangrenous, purulent, or perforative appendicitis mentioned chills or chilliness as having been experienced at the very beginning or in the first few hours of the attack. Where a history of such a chill is obtained he now urges operation as more imperative and anticipates drainage as being necessary. Where an icebag or cold had been applied before operation there was noticed a lack of effort on the part of nature to wall off the appendix from the rest of the abdominal cavity, and the organ was frequently found much congested, perforated or gangrenous. Where, however, a hot water bag or moist heat had been used a greater attempt toward walling off was manifest. Thus, use of the icebag seems harmful—especially if prolonged. Acute pain stopping in twenty-four to forty-eight hours, with marked rigidity, suggests gangrene or acute stasis and is often followed in twelve to twenty-four hours by sudden pain indicating perforation. Temperature and pulse rate are untrustworthy as indicators of safety. Gangrenous and purulent appendixes may coincide with normal temperature and pulse; again, in three cases with a temperature exceeding 103° F., the writer found appendixes only markedly congested, and the temperature dropped to 99.5° in twelve hours after operation. Rigidity and one finger point tenderness are less pronounced in acutely inflamed retrocecal appendixes than in appendixes elsewhere situated; rectal or vaginal examination elicits extreme tenderness in these cases. Nausea or vomiting exists in every attack of true acute appendicitis. Warnshuis places no dependence on the leucocyte count. When appendicitis has been diagnosed one should operate promptly, regardless of the number of hours it has existed. It is unjustifiable not to advise operation because a case is mild. If the appendix is regularly removed, convalescence is hastened and secondary operations are obviated. When drainage is required, abundant means of drainage should be provided. The author always inserts a cigarette drain in acute cases where serous exudate is present, to be removed usually in forty-eight hours. Where the appendix is distended with pus, with free serum present, a double cigarette drain is inserted. In walled off gangrene or pus cases, two split tubes are used. Where there is free pus, no attempt to suture is made, the wound being merely packed and free drainage secured with split and perforated rubber tubes. Sloughing of stitches, after a wound is partly sewed, is successfully obviated by means of seventy per cent. alcohol compresses, changed twice daily. One should not attempt early removal of drainage, and should avoid meddlesome postoperative care.

Contributions to the Study of Shell Shock.—Charles S. Myers (*Lancet*, Sept. 9, 1916) concludes from a study of a large number of cases showing mutism, dysarthria and aphonia that they are not due immediately to such factors as violence, gas poisoning, or physical causes, but are the result of functional inhibitions. These inhibitions may usually be traced to intense fear or horror, but may occasionally be due to conditions in which consciousness is so quickly lost that no emotional experiences can have been felt by the patient. These disturbances are not generally the result of suggestion or association, although previous experience or congenital tendencies may modify their form. They are also not due to a fixed idea in the ordinary meaning of the term, since there is no evidence of a disordered volition. They are due primarily to a derangement of the conscious and unconscious processes which underlie the personality. The inhibitions themselves may be of several grades, but in every case are purely functional and depend upon the personality of the subject at any given moment. The personality itself may be affected by sleep, light anesthesia, hypnosis, strong emotion, or momentary lapses of attention. The disturbances are not maintained or evoked by fear alone; other emotions such as horror, grief, disappointment, and anxiety play their parts.

An Ophthalmic Compressor for Eliciting the Oculocardiac Reflex.—J. Roubinovitch, at a meeting of the Académie des sciences, Paris (*Presse médicale,* August 10, 1916), referred to the physiological effects of pressure on the eyeballs which, under normal conditions, causes a slowing of from four to ten beats a minute in the pulse rate, and in various pathological conditions either a more pronounced slowing, an absence of slowing, or an actual acceleration. The customary method of eliciting the reflex by having an assistant press upon the eyeballs with his fingers is disadvantageous in that the pressure made varies with the assistant and at different times with the same assistant, cannot be exactly measured, may convey infection, and requires the services of a third person. Roubinovitch has devised an instrument free from these defects, consisting of a species of spectacles with supports designed to rest on the forehead, nose, and eyes, readily adjustable, and permitting the application of any desired degree of pressure on the eyeballs. The pressure pads are so disposed that the instrument can be adjusted immediately for certain pressures and the pressure removed promptly when desired. In normal subjects the apparatus produced the oculocardiac reaction exactly as obtained by digital compression. In a number of nervous conditions, such as epilepsy, pulse acceleration was induced in the majority of cases.

Cardiac Rhythm in Soldiers in Active Service.—Léon Binet (*Presse médicale,* August 10, 1916) points out that in the soldier, after temporary arduous exertion there may appear either, 1, a state of asystole with uncountable, thready pulse, possibly soon followed by death; 2, paroxysmal tachycardia, easily relieved by the swallowing of a large bolus of dry bread or by exerting pressure on the eyeball; or, 3, a condition of heart insufficiency with marked arrhythmia and tachycardia, due primarily to insolation. After physical overwork lasting several days, on the other hand, perhaps with sleepless nights, a different condition is observed. Examining a regiment of men in peace time the author found seven per cent. of the men with a pulse rate below seventy; a resting regiment examined in January, 1916, showed similarly six per cent. of men with the pulse below seventy; examination of one hundred men after a very active period, however, during which these men had had to fight day and night and execute other arduous tasks, showed fifty-six men with a pulse below seventy, including twenty with pulse at fifty-five or lower. The existence of a fatigue bradycardia is thus demonstrated. Curiously, the temperature in these overworked soldiers with a pulse rate of sixty or sixty-five is sometimes above normal—38° or 38.5° C. Feeling the pulse for information as to the presence or absence of fever in such subjects is, consequently, misleading. The effects of psychic tension or shock on the pulse rate such as arises from being heavily bombarded with shells, bombs, and torpedoes, was studied in ten subjects. In two there was no change, in five there was a more or less marked slowing, e. g., from seventy to fifty, and in three an acceleration, e. g., from normal to 120. Acceleration seemed most likely to occur in men who had just reached the front or were only moderately courageous. In some cases pulse reactions of this type persist a long time after, as in a patient of Déjerine, whose pulse, after a psychic shock, showed a permanent tachycardia of 160 and at times 180. Sustaining a wound was found usually to increase the pulse rate to ninety, 100, or 110 for several hours, except in men with dangerous cranial wounds, in whom it dropped to sixty-five or fifty-five, and in cases of chest wound with cardiac implication, e. g., a hemopericardium. Explosion of a large shell close at hand caused pulse changes according to whether vagal or sympathetic excitation took place. Eight men in a series of sixteen showed acceleration to between eighty and 100; five, an irregular rhythm with a rate of eighty to 120, and three, a slowing to fifty-six or sixty. Airmen who have just executed a rapid descent or ascent show a slowing, e. g., from seventy-five to fifty-six, due to vagus excitation, which is likely to be associated with low blood pressure and a tendency to syncope (aviator's disease).

Uremia.—Nellis B. Foster (*Jour. A. M. A.,* September 23, 1916), after careful analysis of cases, divides uremia into three distinct types, dependent upon the nature of the functional defect in the kidney. These are: 1. The urinary poisoning of Ascoli, or retention type, which is marked by progressive asthenia and anorexia, stupor and death. 2. The cerebral edema type, due to salt and water retention with edema and symptoms much like those in the first type, but of slower development. Convulsions are absent from both of these forms. 3. The toxic type, or epileptiform uremia, with nitrogen retention and the formation of a toxic body in the blood. The presence of such a toxic body has been demonstrated by the author by isolating it in crystalline form from the blood in fatal cases. The administration of this body to animals kills them with symptoms of dyspnea, defecation, convulsions and coma. Although cases are to be found in which the type is clear, the usual condition encountered is one in which the types are mixed, one type, however, usually predominating in the clinical picture.

Examination of Gastric Contents in the Cardiopath.—A. G. Brown, Jr., (*Virginia Medical Semi-Monthly,* July 21, 1916) refers to the palpitation, tachycardia, bradycardia, arrhythmia, Stokes-Adams syndrome or breast pang frequently accompanying and apparently excited by gastric conditions manifest in such symptoms as eructations, pyrosis, distention, so called gastralgia, nervous vomiting, etc. By careful study of the stomach contents of heart cases he finds much benefit can be obtained in removing not only distressing, but actually dangerous cardiac signs and conditions. While the introduction of a stomach tube or a duodenal tube or bucket is contraindicated in some serious heart maladies, many cases remain in which their use with average skill subjects the patient to no new danger. Chronic gastrorrhea (Reichmann's disease), characterized by epigastric fullness and burning pain appearing usually one or two hours after eating, with relief when copious vomiting of greenish watery fluid occurs, is not infrequent in cardiopaths who during the paroxysms may suffer greatly from dyspnea and palpita-

tion as a result. In such cases heart remedies prove of little use unless the gastric condition is treated by dietetic and medicinal measures also, with or without gastric lavage and physical treatment. Test meal examinations reveal imperfect starch digestion, but meats and fats may be freely used. Frequent, small, dry feedings were found by the writer to give good results, with liquids permitted only in moderation. Lavage, when used, is practised before retiring, or before breakfast, or both. Chronic acid gastritis (hyperchlorhydria), with secretion of gastric juice normal in amount but hyperacid, is also a complicating factor in the cardiopath, causing epigastric distress or pain at the height of digestion, usually with gaseous distention, which aggravates the cardiac symptoms and excites distinct heart attacks. Success in such heart cases is largely dependent upon examination of the stomach contents, as it is also in those complicated with achylia gastrica, manifest in anorexia, pressure sensations, eructations, pain after eating, and diarrhea, due to patulence of the pylorus from absence of hydrochloric acid. In these cases foods of animal origin are to be prohibited and ascending doses of dilute hydrochloric acid given. Acute gastric dilatation occurs at times as a serious complication of heart disease, and requires immediate lavage and evacuation of the overloaded stomach. Brown finds the duodenal tube more useful in examining the gastric functions than the ordinary stomach tube. By its use serial examinations of fractional amounts of the gastric contents may be made throughout gastric digestion and more accurate study and treatment therefore carried out. Patients, moreover, submit to it more readily than to the stomach tube.

Differential Diagnosis of Tuberculosis of the Lungs.—E. Rist (*Presse médicale,* July 24, 1916) discusses, in particular, cases of persistent cough free from tubercle bacilli in the sputum, with or without slight and transitory physical signs suggestive of tuberculosis in one of the apices, and with lungs absolutely clear upon x ray examination. Too often a diagnosis of probable tuberculosis is made in cases such as these, owing to insufficient care in examination. The cough in such instances may be due actually to some cardiac affection, especially mitral stenosis, to chronic nephritis, to gastric atony with ptosis, or to mild exophthalmic goitre. As Pierre Marie has pointed out, many cases of the later variety exhibit a dry, fatiguing, and very persistent cough, the diagnosis, in the absence of distinct thyroid enlargement, requiring careful examination for tremor and the signs of von Graefe and of Moebius, together with radiography of the thorax and sputum examination for bacilli. Much more frequeutly mistaken for tuberculosis, however, especially in the male sex, are conditions due primarily to various chronic nasal and pharyngeal disorders, often hardly noticed by the patients themselves. Many of these patients are accustomed to hawking up in the morning more or less thick, sometimes blood stained mucus; they catch cold easily, but complain only of the attendant, persisting cough, which renders them apprehensive of serious thoracic complications. In other coughing patients, an atrophic rhinitis is the primary factor. Often the mere external conformation of the nose should suggest, to the alert physician, morbid conditions within, such as excessive narrowness of the cavities or a deviated septum. In most chronic nasal cases the voice shows the peculiar change of quality termed rhinolalia, due to altered resonance in the nasal cavities, together with an habitual cough, either dry and paroxysmal, or loose and productive, and even at times associated with hemoptysis, due to varicosities of the tongue or trachea, the result of the chronic inflammation of the mucosæ kept up by the nasal condition. Catarrhal laryngitis and bronchitis, indeed, frequently accompany cough of nasal origin. At times there are physical signs of bronchitis restricted to one portion of a lung, often mistaken for tuberculous involvement unless due attention is paid to accurate percussion, x ray examination, and sputum examination. Fever, dyspnea, and pain may coexist. A frequent source of error is the diminished breath sounds at the apices due to the imperfect filling of the lungs owing to chronic nasal disease. The importance of nasal conditions, especially adenoids, in causing cough in children is clearly realized by all, but not so in adults. When the existence of nasal trouble has been detected by the general practitioner, the case should be referred to the specialist for more precise diagnosis and treatment. The rapidity with which an obstinate cough will disappear upon removal of a hypertrophied turbinate or spur or arrest of a chronic sinusitis is astonishing. Rhinologists themselves fail to realize the pronounced influence exerted by these affections on the bronchial tree.

A New Clinical Hemoglobinometer. — H. Haessler and H. S. Newcomer (*Archives of Internal Medicine,* June, 1916) have modified the Sahli hemoglobinometer in such a way as to secure the advantage of comparison of the specimen under examination with an interrupted series of standards, thus facilitating exact estimate of the hemoglobin value of the specimen. Instead of the single standard tube, eleven graded comparison tubes are used, the densities of which correspond to readings varying by ten from ten per cent. to 110 per cent. hemoglobin. The standard fluids are made up according to Sahli's specifications, the tube marked 100 per cent. containing in 10,000 c. c. the equivalent in hematin hydrochloride of 17.2 grams of hemoglobin, which is the standard amount of hemoglobin in 100 c. c. of blood. The details of the preparation of the several standard tubes are given. Beads are enclosed in the tubes so that the contained fluid can easily be rendered homogeneous by shaking. The tubes are arranged in regular series in a rack, with intervals such that the comparison tube can be fitted in between any two of them. Dilution of the patient's blood is well done with the ordinary red blood pipette, decinormal hydrochloric acid being used as diluting fluid. Diluted one in 100 the blood is dropped into the comparison chamber. On placing the tube at different points in the rack the point at which the progressive shading in the series of tubes becomes harmonious is readily found, and the amount of deviation from one of the multiples often estimated. The readings can be made in any light and with certainty to a multiple of five, that is, to within 2.5 of the correct percentage.

Röntgenological Shadows Associated with Subdeltoid Bursitis.—John McWilliams Berry (*American Journal of Orthopedic Surgery,* August, 1916) reports four cases of subdeltoid bursitis, all of which, upon x ray examination, showed a shadow in the bursal region which disappeared under simple treatment. He also reports two other similar cases, one over the greater trochanter of the femur, the other at the knee joint, and observes that the deposit may appear quickly after a trauma and disappear in a short time.

Arthritis deformans.—E. Senger (*Berlin. klin. Woch.,* March 6, 1916) shows that so called arthritis deformans is probably not an entity, but is rather a group of anatomical changes which may arise from many different causes. Among cases presenting the typical clinical and röntgenological pictures of arthritis deformans are many due to trauma, to syphilis, to gonorrhea, and to other infections. A considerable proportion of such cases is curable and it is, therefore, of prime importance to discover the cause in any given case before considering it as incurable.

Case of Fracture of the Odontoid Process of the Axis.—Prescott LeBreton (*American Journal of Orthopedic Surgery,* September, 1916) reports the case of a man, twenty-two years of age, who was admitted to the hospital two weeks following injury with a fracture at the base of the odontoid process of the axis. The patient showed deformity; fixation of the head slightly to the left and with chin up; slow pulse; and complained of constant pain and local tenderness. The patient reduced the fracture himself one night by twisting his head straight. Recovery with good function followed.

An Early Type of Gallbladder Disease.—Russell S. Fowler (*Archives of Diagnosis,* July, 1916) lays stress on a condition characterized symptomatically by an occasional brief colicky cramp in the epigastrium, sometimes associated with tenderness over the gallbladder—caused by temporary blocking of its neck—and at times radiating to the back. If passage of a small stone through the ducts is taking place, there is more severe pain and sometimes temporary jaundice. The actual condition of the gallbladder in these cases (cholecystitis catarrhalis subacuta) is merely one of infiltration with leucocytes, without any gross pathological change. The organ is not abnormally distended. Careful palpation may show small calculi but is not trustworthy. The diagnosis is verified only by opening the gallbladder and inspection of its interior by one who has already seen the condition. Enlargement of the gland of the cystic duct is sometimes found. When the attacks of pain are frequent—every few months—whether they are disabling or not, the operation is to be advised in this class of cases. If all stones present can be readily removed without trauma and there is absolutely no gross change in the mucous membrane, cholecystostomy is in order; otherwise, cholecystectomy. Fowler prefers the latter operation, believing these cases to represent the initial stage of the ordinary calculous gallbladder disease. Thus performed early, the operation will obviate a great deal of the customary discomfort and the restrictions as to mode of life in cholelithiasis.

Visceroptosis from the Radiographer's Viewpoint.—Fred H. Baetjer (*American Journal of Orthopedic Surgery,* September, 1916) believes that the condition is incidental and has little or no bearing upon the development of spinal lesions.

Anatomy of Visceroptosis.—W. E. Sullivan (*American Journal of Orthopedic Surgery,* September, 1916) believes that the support of the abdominal viscera is dependent upon the shape of the abdominal cavity and the condition of the muscles, ligaments, vessels, and of the viscera themselves.

Role of Visceroptosis in the Etiology of Arthritis deformans.—David Silver (*American Journal of Orthopedic Surgery,* September, 1916), admitting that the intestinal tract is one of the routes of entrance of the infecting organism of arthritis deformans, points out that then the danger of contracting the disease is greater if visceroptosis develops with possible stasis and interference with glandular secretions.

Medical Aspects of Visceroptosis. — Henry Wald Bettmann (*American Journal of Orthopedic Surgery,* September, 1916) considers the acquired type of visceroptosis the only true clinical type, and the so called congenital form could be better named habitus asthenicus, as the malposition of the abdominal organs is but one defect of the many. He condemns the "mechanistic conception of disease" and states that every case is an individual study.

Visceroptosis as a Variation from an Anatomical Norm.—Robert B. Osgood (*American Journal of Orthopedic Surgery,* September, 1916) presents a general discussion with historical, anatomical, physiological, röntgenological, clinical, surgical and orthopedic evidence. He is certain that visceroptosis may be present without symptoms and that it is incidental. He thinks it most difficult to restore a patient to the normal, but it is quite possible in many cases to relieve the symptoms.

Prevalence of Chronic Mouth Infections.—Frederick B. Moorehead (*Jour. A. M. A.,* Sept. 16, 1916) reports 700 cases subjected to careful examination to determine the incidence of chronic alveolar abscess occurring about the apices of the teeth. This form of chronic infection was found to occur in from sixty-nine to eighty-nine per cent., depending upon the class of patients. Thus in a large group of hospital cases of chronic arthritis abscesses were found in eighty-nine per cent.; in a second group, containing no cases of arthritis, the incidence of abscess was seventy-four per cent., and in a group of private cases it was sixty-nine per cent. It was only in adults that these abscesses were found of much importance as a source of systemic or metastatic infection, since in earlier life the tonsils far outweighed the teeth as portals of infection. The age period from twenty-five to sixty years was found to be that of greatest danger from the teeth, but even edentulous jaws harbored sealed abscesses where the teeth had been. A majority of the abscesses were found about teeth previously subjected to treatment of the root canals. The importance of proper root canal treatment is obvious. The most satisfactory means of diagnosis, as well as of determining the extent of tissue destruction, is by x ray examination.

Proceedings of National and Local Societies

THE AMERICAN ASSOCIATION OF IMMUNOLOGISTS.

Third Annual Meeting, Held at Washington, D. C., May 11 and 12, 1916.

The President, Dr. J. W. Jobling, of Nashville, Tenn., in the Chair.

(*Continued from page 670.*)

Localization of a Streptococcus in Animals from a Case of Recurring Neuritis and Myositis (*Continued.*)—Dr. Edward C. Rosenow, of Rochester, Minn., pointed out that the cavity in the tooth, judging from the character of the filling and the bacterial flora, was quite unable to heal for mechanical reasons. This appeared to afford a culture medium for the growth of the streptococcus. From stimulation of the defensive mechanism in the patient during the attacks active growth appeared to be held in check and the symptoms disappeared in consequence, only to reappear later from recurrence of active growth and localization of the streptococci when the immunity was low. The improvement in the patient since the extraction of the tooth appeared to be due to the removal of this focus and to prolonged artificial stimulation of the defensive mechanism by means of autogenous vaccines, which, it was hoped, would lead to the destruction of all the streptococci in the muscle and dental nerves, and result in the ultimate recovery of the patient. The isolation of the streptococcus from so many places would probably make recovery difficult.

Dr. George W. Wheeler, of New York, stated that streptococci were usually classified, according to their effects on blood agar plates, as hemolytic or nonhemolytic. The nonhemolytic varieties had been further classified according to their fermentation reactions with different sugars, but wide variations were found by these methods, due to variations in the organisms themselves and to chemical changes in the sugars during the process of sterilizing the media. None of these differential methods gave any clue as to what the streptococci would do when they were in the animal body.

Doctor Rosenow's work began where these methods ended; his original idea being that organisms growing in the human body had certain delicate, transient, biological activities which were soon lost when the bacteria were grown on artificial media. In order to demonstrate these activities, the organism must be transferred from the human body to animals, the original culture from the patient being used for inoculation, and the lesions in these animals studied. Animal inoculation with recently isolated strains, grown under certain definite conditions, showed that the lesions produced in the animals were often similar to those in the patient from whom the organisms had been obtained. Whether this was a mere coincidence or was due to a specific affinity which the organisms had for certain tissues, could be determined when a great deal of experimental evidence of this kind had been presented and carefully examined. Control animals were necessary in order to rule out the possibility of the lesions being spontaneous. The speaker said that in work which he had done, according to the methods described by Rosenow, with streptococci from nine cases of arthritis and endocarditis, lesions in joints were found in the animals in seventy-five per cent.; in muscles, sixty-three per cent.; in the heart, fifty-five per cent.; while in other organs lesions were relatively infrequent; appendix, six per cent.; stomach, eleven per cent.; brain and cord, six per cent.

Dr. Joseph Head, of Philadelphia, observed that the mouth was such an excellent culture oven that any germ might occasionally be found in it. Obviously only a small percentage of the germs introduced into the mouth found lodgment within the tissues and became pathogenic. In making his bacterial examinations for autogenous vaccines, he cauterized the surface of the infected spot with an electric cautery until it turned slightly white, and then extracted blood from the tissues through the cauterized spot with a hot platinum spear. Out of 400 such examinations he found streptococci in ninety-five per cent., Bacillus influenzæ and Micrococcus catarrhalis in about seventy-five per cent., while the pneumococcus appeared in about twenty-five per cent. The pus taken from a pus pocket in one case had eighty per cent. of Pneumococcus mucosus in the material; the rest contained streptococci, Bacilli influenzæ, and Micrococci catarrhales. After giving ten doses of a vaccine made of these, the mouth healed and the pneumococcus was not discovered again in the various pockets. The work of Rosenow concerning the pulp infection from the circulation was valuable because it gave a quietus to those who thought it unwise to take out a live infected nerve when it was evident to all thoughtful observers that a living pulp might be a great source of systemic disease.

Dr. Oscar Berghausen, of Cincinnati, wished to congratulate Doctor Rosenow upon the work he had done. Last summer he had had the opportunity of seeing a case of generalized herpes of the extremities and of the lips, and he had isolated a definite organism, Streptococcus pyogenes. In such cases there was a bad prognosis, most of them being fatal inside of one or two years. In this case, an autogenous vaccine was administered and was followed by recovery in about two months. The patient was relieved for eight months, when a slight recurrence took place.

Dr. E. C. Rosenow, of Rochester, Minn., preferred using the terms "green producing" and "hemolyzing streptococci" instead of Streptococcus viridans and Streptococcus hæmolyticus, because there appeared to be numerous variants of each strain, particularly of the former, and because one might be transmuted into the other. He appreciated highly the splendid work of Cole and Dochez and their associates at the Rockefeller Institute, on the classification and immunological observations on pneumococci; pneumococci showed in his hands, as with these worker's fixed characters when grown in

the usual way, but when pneumococci were placed under special environment they lost their specific glutinating reactions and took on new features; they might even be converted into hemolyzing streptococci.

The demonstration of living streptococci in the muscles in the case reported during the quiescent interval was of importance, and in accord with similar findings in ulcer of the stomach, chronic rheumatism, cholecystitis, etc., because it showed that not too much should be expected from the removal of the primary focus in diseases which were characterized by exacerbations and quiescent intervals, and served to explain the nature of the exacerbations and remissions.

The Epidemiology of Lobar Pneumonia.—Dr. A. R. Dochez, of New York, presented a study of pneumococci isolated from patients with lobar pneumonia which had shown that the majority of these organisms fell into definite biological groups. In view of these constant differential characters of the pneumococcus, it had been deemed advisable to study the pneumococci occurring in normal mouths. It had been commonly assumed that infection in pneumonia was autogenic and occurred from invasion of the lungs by pneumococci habitually carried in the mouth. If this was so, they should find the same types in the normal mouths as occurred during disease. Examination of a series of normal individuals showed this not to be the case. The two types of pneumococcus responsible for the majority of the severe cases of lobar pneumonia were not found in the normal healthy mouth, except in instances where the patient harboring the organism had been in intimate association with lobar pneumonia. When such a condition existed the organism found in the normal mouth invariably corresponded in type to that found in the lung of the patient. These studies made it probable that the majority of the cases of pneumonia depended either on direct or indirect contact with a previous case.

Specificity of Pneumococcus Types; Fatal Infection Due to One Type in a Horse Producing an Antiserum of High Titre to Another Type.—Dr. A. P. Hitchens, Dr. E. K. Tingley, and Dr. George Hansen, of Glenolden, Pa., said that the horse in question had been under treatment for several months with a pneumococcus corresponding in serological reactions with Neufeld type 1. The last injection was given about one month before death and the bleeding subsequent to this showed that the potency of the serum of this horse was such that 0.00001 c. c. of the serum would protect a mouse against a fatal dose of pneumococci of the homologous type.

Blood culture three days before the death of the horse showed the presence of a pneumococcus not corresponding in type with that with which the animal had been injected. The pneumococcus recovered was still under examination. It did not correspond with type 2 and was not the mucosus. It did, however, bear strong resemblance to some strains of pneumococci obtained from equine infections. Autopsy of the animal showed pulmonary consolidation and inflammation of the mucous membranes lining the respiratory passages.

Dr. Edward B. Vedder, Captain M. C., of Washington, D. C., was unable to understand why he had been asked to discuss this paper, except upon the theory that, never having done any work with pneumonia, he would be unhampered by the limitations necessarily imposed by exact knowledge. Those who had worked with a subject were badly handicapped. They would like to make positive and definite statements, but the wider their work had been, the harder become such categorical statements, since they must always be qualified by the observation of stubborn facts that apparently ignored the hypothesis that was supposed to govern them. They had known all about pneumonia for a number of years. They learned a long time ago that many, perhaps a large proportion of normal persons carried the pneumococcus in the sputum. Of course it was plain that if they became suddenly chilled, or their resistance was greatly lowered, that they would manifest pneumonia. This was a very comfortable theory. Pneumonia was nobody's fault, and they did not have to do anything except die when it came their turn. Now Doctor Dochez and his associates came along and told them that this was wrong. If Doctor Dochez was right, what were they to do? Some of them had begun already to make antipneumococcus serums one, two, and three, for treatment. But this method of treatment seemed a little discouraging in view of the fact that it would be a long time before the practising physician would recognize Pneumococcus No. 1 from Pneumococcus No. 2 when he met it on the street. This was a difficulty which could be obviated by cooperation with the laboratory. But this entailed delay, and if one or two days elapsed while the diagnosis was being made, they could not expect the results from the serum to be very striking. Perhaps a polyvalent serum was the answer.

In any case, prevention was much more important than cure, and Doctor Dochez's work opened up a most hopeful vista. It meant that every case of pneumonia was due to and might be traced directly or indirectly to a previous case of pneumonia. From a sanitary point of view pneumonia must be treated just like any other infectious disease in which the infecting agent was transmitted by the buccal secretions of those affected, and the present widespread prevalence of pneumonia was probably due directly to their present policy of *laissez faire*. Time was lacking to go into the details of sanitary measures which should be taken for the prevention of pneumonia. But when the various boards of health came to life they might expect to see something like the following measures enforced: 1. Notification of all cases of pneumonia. 2. Prompt visitation by a health officer, collection of specimens, and laboratory diagnosis of the type of organism present; *a*, in the patient; *b*, in the contacts. 3. Isolation of the patient and of any contacts who harbored the type of pneumococcus found in the patient. 4. A negative culture requirement before the patient or carriers were permitted to mingle with the community. This might appear rather stringent to some of them at first thought, but when they remembered the great mortality of pneumonia it was evident that if there was any chance of limiting its incidence they must take advantage of it.

Dr. Judson Daland, of Philadelphia, desired to express his personal thanks to Doctor Dochez for

demonstrating so clearly that the ordinary pneumococci found in the mouth were not responsible for pneumonia, and therefore the disease should be considered still to be usually transmitted by contact, and to demand isolation. Doctor Rosenow's contribution was along the lines with which he had made them familiar during the past several years. In the case reported, however, he had shown by animal experimentation that streptococci recovered from an infected root of a tooth were able to produce inflammation of the dental pulp with hemorrhages; and from this pulp he had recovered living streptococci. The evidence he presented proved that in some cases infection of the pulp of a root, which could easily evolve into periapical abscess, might be hematogenous in origin. Hitherto, most observers had believed that infected root canals and periapical abscesses were chiefly due to accidental infection when these canals were opened in consequence of caries, or when they were emptied of their contents, and that periapical abscesses also occurred by contiguity, i. e., periapical abscess in one root infected another in the immediate neighborhood. This question was of unusual importance because of the proved relationship of periapical abscess to many systemic diseases, and lay open to suspicion, not only the roots of capped or devitalized teeth, but also teeth that had shown no caries. In such cases, however, they naturally expected that pain in the infected root would lead to diagnosis of acute infection by way of the blood; and that such a history of pain in a root made the root a source of infection. Naturally, the value of these observations would be increased by confirmatory evidence; as this case had been carefully observed by Doctor Rosenow and the cultural and experimental results had been obtained by him, they were worthy of their acceptance because of the experience which he had had with such questions in many parts of the body, an experience which now extended over several years.

Dr. E. C. L. Miller, of Richmond, Virginia, stated that Dr. Frederick M. Hanes, of Richmond, had been doing some work with pneumonia along these lines. He had kept mice and diagnostic serums on hand and had treated some patients with the curative serums. However valuable this work might be from a scientific and experimental standpoint it was evidently not practical. It could be done only by an expert. He wished to inquire what had been done to make it available for the general practitioner.

Typhoid Fever.—Dr. A. L. Garbat, of New York, said that their experiments with reference to the complement fixation test after prophylactic typhoid vaccination might be summarized by stating that a positive complement fixation test after prophylactic typhoid immunization was not a regular occurrence, as it was during or after typhoid fever. This point might be of aid in deciding for or against the diagnosis of typhoid fever in an inoculated individual still having a positive Widal and ill with a suspicious fever and negative blood culture. A positive complement fixation test was obtained usually after three injections with a polyvalent vaccine; two injections with this same vaccine or three injections with the single strain vaccine (Rawlings) gave hardly any complement fixation.

On account of the many difficulties in the way of stool examinations in typhoid fever, they had attempted direct examination of the bile removed from the duodenum. This had the advantage of avoiding the great number of contaminating bacteria in the stool; no special media were essential and the bacteria were present in great numbers. They had found that cultures of the duodenal contents (bile) removed by means of the duodenal tube seemed to be a more trustworthy and simpler method for the detection of typhoid bacilli than stool examinations. The serum from convalescent typhoid patients had been employed with distinct benefit in three very severe acute typhoid cases.

Dr. A. H. Sinclair, of Honolulu, Hawaii, was prone to believe that after the use of the typhoid vaccine, when typhoid fever had occurred, there must have been some fault either with the technic or with the vaccine. He did not believe that any patient who gave a positive Widal after typhoid could again contract the disease for many years thereafter. The isolation of the bacillus from the blood or from the stools was certainly superior in cases recommended for the applicability of the complement fixation test.

Dr. A. Zingher, of New York, had used at the Willard Parker Hospital, during the past eighteen months, intramuscular injections of fresh whole blood obtained from convalescent scarlet fever patients. The blood was either citrated or noncitrated. Distinct beneficial effects were noted in toxic cases after injections of blood obtained from patients who were in the third to fourth weeks of convalescence. In a recent case, a very striking improvement was seen from 300 c. c. of fresh blood obtained from a three months' convalescent donor. If it should prove that convalescent blood had therapeutic value even as late as six months after the disease, then the opportunity for employing the treatment would become much greater. Convalescent blood could be used not only in diseases that resulted in a more or less permanent immunity, like scarlet fever, typhoid, and measles, but also in diseases followed by only a short protection, like erysipelas and pneumonia. The blood in these cases should be obtained from donors not more than two to three weeks convalescent. A striking recovery followed in a six year old child suffering from a severe attack of erysipelas, whom he had injected with 210 c. c. of fresh convalescent blood (seven days).

He had used intramuscular injections of normal blood in late septic cases of scarlet fever. In these the toxemia of scarlet fever was no more in evidence. Injections of normal blood, which could be readily obtained from relatives, were given in quantities of 120 to 240 c. c., repeated every four days. Such blood was not given for any specific action, but for its general stimulating and nutritive value, which helped to tide the patient over a critical period.

Dr. William Egbert Robertson, of Philadelphia, had treated a number of patients in the wards of the Episcopal Hospital by using subcutaneously

serum obtained from convalescent typhoid and pneumonia patients, which was then administered to patients at that time ill with the respective diseases. Fifty c. c. of the serum was given as a dose and repeated several times, but the results did not warrant continuance. Much better results followed in erysipelas, where, after raising blisters, he had injected the serum thus obtained directly into the vein of the same patient or of other patients with erysipelas. Some of these serums were inactivated, while others were not, but as far as typhoid and pneumonia were concerned, no apparent benefit resulted. Doctor Robertson asked the reader of the paper whether his patients were fed by the high calory method, or whether milk alone was permitted, as these latter were virtually starvation cases, since the majority refused to take milk in any amount. Doctor Robertson said that it had been his experience with a large number of cases carefully studied bacteriologically by Dr. C. Y. White, pathologist to the Episcopal Hospital, that the well fed patients proved very exceptionally to be ultimate typhoid carriers, while the virtually starved patients, or those fed on milk, frequently became carriers. It was nothing more than an assumption, but it seemed logical to believe that those well fed acquired a greater resistance and a higher antibody formation.

Dr. A. L. Garbat, of New York, said that all the cases at the German Hospital were placed upon the high calory method of feeding, and the physicians had practically abandoned the starvation treatment. Whether typhoid carriers were more frequently those with the high calory value or those under the so called starvation treatment, he did not know.

Standardization of Antimeningitis Serum by Animal Protection Tests.—Dr. George H. Robinson, of Glenolden, Pa., stated that variable ability to produce agglutinins and complement fixing bodies had been noted among horses under antimeningococcic treatment. An animal protection test seemed desirable as a measure of the potency of the serum. A sixteen hour old culture of meningococci on serum dextrose agar was necessary for the test. Suspended in fresh guineapig serum, diluted three times with 0.85 per cent. salt solution, most strains were virulent for white mice. If antimeningococcic serum was injected two hours previous to the injection of the cocci, considerable protective power could be demonstrated. The amount of serum used had been invariably 0.5 c. c. Culture was used in 0.5, 0.25, 0.12, etc., amounts.

By this method the amount of protection afforded by different serums very closely paralleled the extent of treatment the horses had received. Agglutinating and complement fixing power showed no correlation with protective power. The test was specific in that different strains of meningococci could be distinguished, as well as the gonococcus. As a routine measure all freshly isolated strains of meningococci were tested with a polyvalent serum and those against which the serum did not protect were incorporated into the treatment of the horses. The polyvalency of antimeningitis serum was of extreme importance.

If the amount of immune serum necessary to protect against one m. l. d. of living culture was considered as a unit, a uniform standardization of antimeningitis serum was obtained. Such a standard meant more to the physician and was a better test of the therapeutic efficiency of a serum than tests *in vitro*.

Dr. Harold L. Amoss, of New York, believed that a discussion of Doctor Robinson's paper was difficult because of the new method used. One of the most important features of any discussion was the influence toward the standardization of the methods employed. Doctor Robinson had used for his experiments a very irregular strain (Isadore) instead of the accepted typical parameningococcus. The speaker was glad that the subject of meningitis had been reopened, because it was evident that there was much to be learned about the preparation and standardization of antimeningitis serum. Therapeutic application had been kept in mind at the Rockefeller Institute, where with Dr. Martha Wollstein, he had been engaged in the preparation of a polyvalent serum. In other words, particular care had been exercised to corroborate their laboratory tests with the therapeutic tests. Animal protection tests had been found to be the least specific of all methods of standardization. He was very much interested in Doctor Robinson's clear cut results in protection tests obtained by diluting the suspension of living meningococci with complement. Recently he had made some protection tests, using young guineapigs, and had found that a univalent antiparameningococcus serum would protect young guineapigs against one infective dose of homologous parameningococcus, and against an irregular strain, though more serum was required for the latter. The same amount of serum did not protect the animal against a lethal dose of a typical or normal meningococcus. He referred to this experiment to show that in his experience the protection tests roughly paralleled the agglutination tests. The reaction and opsonization were not as specific as the agglutination reaction. In human cases of meningitis, though treated with antimeningitis serum, the meningococci persisted in the spinal fluid. The strains of meningococcus isolated from these cases were not agglutinated in the serum used. When a more polyvalent serum, and one which agglutinated the particular strain, was used in treatment, the organisms disappeared, the fever abated, and recovery was uneventful. As agglutination tests paralleled other tests and were more specific than the latter, agglutination should be used in the standardization of antimeningococcic serum. The power to agglutinate in high dilution all known varieties of the meningococcus gave them the best idea of the value of antimeningitis serum.

Dr. James W. Jobling, of the Vanderbilt School of Medicine, Nashville, Tenn., recalled that the existence of parameningococcus strains was not recognized when they began the preparation of the antimeningococcus serum. They realized, however, the necessity of using many strains of organisms. Their results with the complement fixation method were unsatisfactory, therefore it was discarded. According to the work done by Amoss, it was possible that some of these results were due to the fact that they were using strains of the parameningococcus. They

were not convinced that the death of guineapigs receiving intraperitoneal injections was due to infection. The clinical picture and the post mortem findings suggested rather an intoxication. Adopting this idea they had attempted to isolate the toxin and use it to standardize the serum, but the results were so untrustworthy that this method was also discarded.

Dr. Harold L. Amoss, of New York, again referred to the meningitis problem that confronted them. An important point was the great value of time in the administration of antimeningitis serum. It had been observed that many hospitals were casual in their specific treatment of acute infections. He believed that the serologists could assist a great deal in this matter by putting forth every effort to make an early diagnosis, by procuring serum immediately, and by delicately impressing upon clinicians the extreme value of early administration.

Clinical Significance of the Wassermann Test.—Dr. Arthur F. Coca, of New York, said they all knew that the Wassermann reaction was a biochemical test; i. e., it was performed with reagents whose chemical constitution was practically unknown, some of them being relatively very unstable bodies. The Wassermann "mixture" was subject to considerable variations, depending upon the particular method or modification of the original technic used and also upon the manner of standardizing the different reagents, as well as upon the quality of the antigen preparation available. On account of the above mentioned technical variations, as well as on account of factors heretofore uncontrolled, there existed a considerable want of uniformity in the results of the Wassermann test. There had yet to be recorded a series of parallel tests carried out by different observers on the same serums in which the results agreed throughout.

As has been pointed out by Uhle and MacKinney, the disagreements were more common in just the cases in which the need of trustworthy information was greatest. The results of the Wassermann test were further vitiated by the fact that it was being performed by an ever widening circle of superficially informed and uncontrolled "technicians." It had been clearly demonstrated that the positive Wassermann reaction was not specific for syphilis. It occurred not only with some regularity in other conditions, but also sporadically in many others. Analysis of its relations to the therapeutics of syphilis showed that in the great majority of instances the result of the test did not influence the course of specific treatment.

The use of the Wassermann test as a legal criterion of eligibility for marriage must be unconditionally opposed.

Analysis of Cases Changing to Wassermann Positive After a Negative Period of Twelve Months or Over.—Dr. Louis A. Levison, of Toledo, had collected sixteen cases fulfilling the conditions mentioned in the title. An analysis of the results of the Wassermann tests in these cases showed that a negative Wassermann, even though obtained over a considerable period of time, could not be considered as a criterion of cure. It was, however, the best index at the present time of the patient's condition, when considered in conjunction with the absence of clinical manifestations. Carefully considered cases over a much longer period of time would be necessary to determine the final position of the Wassermann as a prognostic agent. Treatment of whatever nature might help to keep the patient Wassermann negative, only to relapse when this was discontinued. In this series all the cases were late or advanced when competent treatment was supplied. They received mercury either in small and inefficient amounts, some not at all, at the time when treatment could have been of value. Many cases coming under his observation which had been treated intensively from the very start with salvarsan and mercurial injections, had gone over one year with negative Wassermanns, and this group, while not considered here, stood in sharp contrast to this series of late cases.

(To be continued.)

Book Reviews

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

A Textbook of Human Physiology. Including a Section on Physiologic Apparatus. By Albert P. Brubaker, A. M., M. D., Professor of Physiology and Medical Jurisprudence in the Jefferson Medical College; Formerly Professor of Physiology in the Pennsylvania College of Dental Surgery, etc. Fifth Edition. Revised and Enlarged. With One Colored Plate and 359 Illustrations. Philadelphia: P. Blakiston's Son & Co., 1916. Pp. xii-776. (Price, $3.)

This well known textbook of physiology, now in its fifth edition, has been subjected to careful revision and in many sections has been entirely rewritten. Among the subjects which have been added, enlarged, or revised, are the metabolism of the food principles: carbohydrate metabolism; the electric currents of the heart and their graphic registration by the electrocardiogram; animal heat; internal secretion; localization of functions in the cerebral cortex; and the autonomic nerve system. In its new form the book should be of added service to the medical student and practitioner. The publishers have also contributed to the success of the work by the excellence of the technical details of printing and binding.

The Mortality from Cancer Throughout the World. By Frederick L. Hoffman, LL.D., F.S.S., F.A.S.A., Statistician, The Prudential Insurance Company of America; Chairman, Committee on Statistics, American Society for the Control of Cancer, etc. Newark, N. J.: The Prudential Press, 1915. Pp. xv-826.

The able statistician, Frederick L. Hoffman, LL.D., has presented in this notable and comprehensive volume the available statistics of mortality from cancer. He treats of increase in cancer, its mortality in different occupations, its importance as affecting life insurance, and of the geographical incidence of cancer throughout the world, its frequency in American States and cities, as well as in foreign countries. He concludes with general observations on the cancer problem. The book contains 554 pages of statistical matter. It presents a full bibliography of writings relating to cancer. The author concludes that the menace of cancer throughout the civilized world is much more serious than has been generally assumed to be the case; that the mortality from cancer is increasing at a more or less alarming rate, and that this increase implies most serious consequences, present and future; that practically all forms of cancer are on the increase, that cancer frequently decreases with diminishing distances from the equator; and that even a very low cancer death rate is not necessarily evidence of the intrinsic untrustworthiness of the returns. With regard to heredity and family his-

tory, some additional observations reemphasize earlier conclusions that the available evidence in this respect is in the negative. The evidence as regards a possible parasitical origin of cancer is held to be inconclusive. The book is of the highest value from the statistical standpoint, for it would be constitutionally impossible for the author to issue any publication lacking in statistical accuracy. It is so inclusive and painstaking that it becomes at once an authoritative reference book for students of the cancer problem. We are constrained to add that from the point of view of the pathologist and histologist, it is a fundamental anachronism, in any serious discussion of disease, to retain in use such a vague word as cancer. Even the author admits the absence of a concise definition of the term. He regards cancer as including tumors (*sic*) of all kinds, whether malignant, benign, or ill defined. Cancer thus defined is a term of popular convenience rather than a scientific designation of disease manifestation, and statistics relating to it possess as much value, and as little, as similar statistics of other general pathological states such as inflammation, insanity, rheumatism, indigestion, and the like. Because of the varying and uncertain implications of the term as employed, the statistics are necessarily unconvincing. The psychologist, neurologist, and sociologist will all take exception to the author's casual dismissal of worry and anxiety as etiological factors of malignant neoplasms, especially of the glandular type. Even the author admits the prevalence of neoplastic diseases under conditions of urban tension.

The book is well written, is almost encyclopedic, is characterized by painstaking and accurate research, and has the delightful quality of stimulating the reader to a critical study of the author's point of view, and to a wholesome intellectual opposition to many statements in his interesting pages.

Practical Massage and Corrective Exercises. By HARTVIG NISSEN, President of Posse Normal School of Gymnastics; Superintendent of Hospital Clinics in Massage and Medical Gymnastics, etc. Revised and Enlarged Edition of the Author's Practical Massage in Twenty Lessons, with many additions. With 68 Original Illustrations, Including Several Full Page Halftone Plates. Philadelphia: F. A. Davis Company, 1916. (Price, $1.50.)

This little book of 212 pages is written, as stated in the preface, with the earnest "hope it will be of value to those who wish to learn in a practical way to treat suffering humanity with mechanotherapy." The author has ignored the time honored recognition of the invaluable fact that the underlying and essential principle of successful therapeutics is correct diagnosis. With haphazard diagnosis any skillful treatment is more apt to be misapplied than efficacious. It is rare that a patient is capable of arriving at a correct diagnosis of his own condition, nor is the author, who is not a physician, qualified to reach a sound analytical decision as to the appropriateness of remedial measures.

The necessity for our comment is to be found in many instances. On page 183, under the heading, appendicitis, we find these words: "If these cases had been treated by massage from the first day of the symptoms, I do not hesitate to say that the appendicitis would have been avoided." Again, on page 203: "I claimed that I would cure any 'lumbago' sent me, in from two to six treatments. . . . In less than a week after this I had six lumbago cases sent to me, each of which were cured in two treatments." The natural inquiry of the reader must be, Were these cases lumbago, or only so called?

The consideration of the treatment of the various diseases by mechanotherapeutic measures sounds like the unwarranted statements made by irregular practitioners, except only in the last paragraph of the book. "*Massage should not be used* in any case of high fever, cancer, ulcers, hemorrhages, infectious diseases, or diseases where the inflammatory products have assumed a quality injurious to the system, nor in most skin diseases."

As the author has been lecturer and instructor of massage and Swedish massage at Harvard University summer school for twenty-four years, we are still more astonished at the contents of the last 104 pages of the book, much of which is at variance with the writings of the medical faculty of the university. The first 108 pages devoted to practical massage and Swedish movements are highly commendable.

Interclinical Notes

An American author has recently favored us with the neologism, peripenic; this violates two rules of derivation in two syllables. The perfectly obvious correct form is circumpenile.

* * *

In the double number of the *Outlook* for July 26th, there were sympathetic editorial discussions of the late Elie Metchnikoff, and of Dr. Simon Flexner's opinions on infantile paralysis. There was an admirable portrait of the Rockefeller Institute expert.

* * *

An excellent paper in the *Outlook* for October 4th is A Word about Criminals, written by George S. Dougherty, chief of detectives in New York city. Mr. Dougherty believes that the ex-convict should have a chance to make good in some new job, and states that it would be cheaper to keep him in jail for life than to treat him as we do now. The peculiarities of the different classes of criminals, as set down in this paper, are extremely interesting; early training seems to have more to do with a criminal career than heredity. The ideals of conduct continually held before a child are what determine his future, or at least his attitude toward society.

* * *

One of the poets contributing to the Conning Tower of the *New York Tribune*, recently wrote of swimming in the village creek, and of digging his toes into the "dirt" alongside. The black loam on the bank of a creek is not dirt; on the contrary, nothing could be cleaner or more appropriate in its place. Perhaps we may excuse the young versifier, who lacked a rhyme. Mr. Robert W. Chambers, however, has no excuse whatever for making exactly the same mistake in a short story in the October issue of *Hearst's Magazine*, where he writes of the dirt instead of the earth which made up the walls of the war trenches.

* * *

In *Commerce and Finance* for September 25th, the editor tells a story of the smuggling into China by the Minister of Justice, no less, of half a million dollars' worth of opium; he remarks: "It would not appear from this that the suppression of the opium trade has been so much of a success as it has been declared or that the people have been freed from the habit to the extent supposed." Our readers will recall, perhaps, that we expressed ourselves very much in the same way when, some months ago, an enthusiastic opium prohibitionist declared that millions of Chinese, on the issuing of an edict, had instantly ceased the use of opium.

Meetings of Local Medical Societies

MONDAY, *October 9th.*—New York Ophthalmological Society; Society of Medical Jurisprudence, New York; Roswell Park Medical Club, Buffalo (annual); Association of Alumni of St. Mary's Hospital, Brooklyn; Williamsburg Medical Society, Brooklyn; New Rochelle, N. Y., Medical Society (annual).

TUESDAY, *October 10th.*—New York Academy of Medicine (Section in Neurology and Psychiatry); Medical Society of the County of Wyoming (annual); Ontario County Medical Society (annual); Medical Society of the County of Schenectady; Medical Society of the County of Rensselaer; Buffalo Academy of Medicine (Section in Medicine); Medical Society of the County of Oneida.

WEDNESDAY, *October 11th.*—New York Pathological Society; New York Surgical Society; Alumni Association of Norwegian Hospital, Brooklyn; Schenectady Academy of Medicine; Medical Society of the Borough of the Bronx; Richmond County, N. Y., Medical Society; Dunkirk and Fredonia Medical Society; Rochester Academy of Medicine; Medical Society of the County of Montgomery; Medical Society of the County of Dutchess (annual).

THURSDAY, *October 12th.*—New York Academy of Medicine (Section in Pediatrics); Gloversville and Johnstown Medical Association; Physicians' Club of Middletown; West Side Clinical Society, New York; Brooklyn Pathological Society; Blackwell Medical Society

of Rochester; Jenkins Medical Association, Yonkers; Society of Sanitary and Moral Prophylaxis, New York; Buffalo Ophthalmological Club; Jamestown Medical Society; Society of Physicians of Village of Canandaigua; Medical Society of the County of Alleghany (annual).

Friday, *October 13th.*—New York Academy of Medicine (Section in Otology); Society of Ex-Interns of the German Hospital in Brooklyn; Flatbush Medical Society, Brooklyn; Eastern Medical Society of the City of New York; Society of Alumni of St. Luke's Hospital; Clinical Society of the German Hospital and Dispensary.

Official News

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers of the United States Public Health Service for the seven days ending September 27, 1916:

Fricks, L. D., Surgeon. Relieved at New York and ordered to proceed to Boston, Mass., to assist in the control of poliomyelitis.

Grubbs, S. B., Surgeon. Directed to proceed to Washington, D. C., for conference relative to the transfer of the Boston Quarantine Station to Federal control.

Hommon, H. B., Sanitary Chemist. Directed to proceed to Salem, Va., and places in that vicinity in connection with studies of industrial wastes.

Kempf, Grover A., Assistant Surgeon. Promoted and commissioned a passed assistant surgeon, effective August 16, 1916.

Leake, J. P., Passed Assistant Surgeon. Directed to proceed to Baltimore, Md., to obtain data for studies of poliomyelitis.

Lloyd, B. J., Surgeon. Directed to proceed to Port Townsend, Wash., to assist in bacteriological examination of passengers on ships from Asiatic ports to determine cholera infection.

Lumsden, L. L., Surgeon. Directed to revisit counties in which studies of rural sanitation have been conducted for the purpose of obtaining data.

McLaughlin, Allan J., Surgeon. Granted one year's leave of absence without pay from November 1, 1916.

Neill, M. H., Assistant Surgeon. Granted one month's leave of absence from September 23, 1916.

Phelps, E. B., Professor. Directed to attend the meeting of the American Chemical Society at New York, September 25-28, 1916.

Pierce, C. C., Senior Surgeon. Directed to proceed to El Paso, Tex., to supervise operations for the prevention of the introduction of typhus fever from Mexico.

Ridlon, J. R., Passed Assistant Surgeon. Relieved from duty at New York and directed to proceed to Baltimore, Md., for duty in preventing the spread of poliomyelitis in interstate traffic.

Smith, F. C., Surgeon. Granted twenty-one days' leave of absence from November 1, 1916.

Sydenstricker, Edgar, Public Health Statistician. Directed to proceed to Washington, D. C., for temporary duty in the compilation of data relating to health insurance; granted four days' leave of absence en route.

Sweet, E. A., Surgeon. Directed to proceed to Baltimore, Md., for conference relative to poliomyelitis situation.

Thompson, L. R., Passed Assistant Surgeon. Relieved from duty at New York and ordered to return to station at Cincinati, Ohio; granted one day's leave of absence en route.

Treadway, Walter L., Assistant Surgeon. Granted one day's leave of absence en route to station.

Williams, C. L., Passed Assistant Surgeon. Directed to assist in making bacteriological examinations of steerage passengers from cholera infected ports in the Orient.

Board Convened.

Board of medical officers convened at the marine hospital, Savannah, Ga., October 2, 1916, for the physical examination of an officer of the coast guard for promotion. Detail for the board: Acting Assistant Surgeon A. B. Cleborne, chairman; Acting Assistant Surgeon L. W. Shaw, recorder.

Births, Marriages, and Deaths

Married.

Boyden-Brix.—In Omaha, Neb., on Wednesday, September 20th, Dr. Henry B. Boyden, of Grand Island, Neb., and Miss Eve Brix.

Dryfus-Ullman.—In New Haven, Conn., on Wednesday, September 20th, Dr. Milton L. Dryfus and Miss Minna Ullman.

Fetter-Mayo.—In Ashland, Ky., on Saturday, September 23rd, Dr. Samuel Pritchard Fetter, of Portsmouth, Ohio, and Mrs. John Calhoun C. Mayo.

Grace-Thomas.—In Burlington, Vt., on Tuesday, September 26th, Dr. Edward S. Grace, of New Britain, Conn., and Miss Isabella Thomas.

Powers-Jordan.—In Boston, Mass., on Wednesday, October 4th, Dr. Edward P. Powers, of Roxbury, Mass., and Miss Alice R. Jordan.

Robbins-Lynch.—In Boston, Mass., on Thursday, September 21st, Dr. Edmund H. Robbins, of Manchester, N. H., and Miss Mary Helena Lynch.

Savage-Eddy.—In New London, Conn., on Monday, September 25th, Dr. C. Grant Savage, of Westerly, R. I., and Miss Caroline May Eddy.

Sullivan-McGuire.—In Tiverton, R. I., on Monday, September 18th, Dr. James E. Sullivan, of Providence, R. I., and Miss Laura N. McGuire.

Williams-Tougas.—In Agawam, Mass., on Wednesday, September 20th, Dr. Abram C. Williams, of Springfield, Mass., and Miss Martha M. Tougas.

Died.

Adcock.—In Hickman Mills, Mo., on Thursday, September 21st, Dr. D. Claude Adcock, of Warrensburg, aged thirty-six years.

Biddle.—In Islesboro, Me., on Monday, September 18th, Dr. Alexander Williams Biddle, aged sixty-five years.

Carswell.—In Jacksonville, Fla., on Thursday, September 14th, Dr. Samuel T. Carswell, aged thirty-eight years.

Everhart.—In Baltimore, Md., on Sunday, September 17th, Dr. George Hauer Everhart, aged forty-nine years.

Gudden.—In Oshkosh, Wis., on Friday, September 15th, Dr. Bernard C. Gudden, aged fifty-nine years.

Hanscom.—In Somerville, Mass., on Wednesday, September 20th, Dr. Sanford Hanscom, aged seventy-five years.

Hibbard.—In Rome, N. Y., on Sunday, September 17th, Dr. Gilbert C. Hibbard, aged eighty-one years.

Kephart.—In Cresson, Pa., on Monday, September 18th, Dr. Thomas A. C. Kephart, of Altoona, aged forty-seven years.

McLeod.—In Milwaukee, Wis., on Thursday, September 21st, Dr. John Alexander McLeod, aged sixty years.

McNamara.—In Denver, Col., on Tuesday, September 19th, Dr. John W. McNamara, aged thirty-nine years.

Miller.—In Jordansville, N. Y., on Thursday, September 28th, Dr. Adam Miller, aged ninety-eight years.

O'Reilly.—In Philadelphia, Pa., on Monday, September 18th, Dr. Thomas B. O'Reilly, aged forty-seven years.

Peters.—In Harrisburg, Pa., on Tuesday, September 19th, Dr. William C. Peters, aged fifty-seven years.

Poindexter.—In Prairie Home, Mo., on Monday, September 18th, Dr. John W. Poindexter, aged sixty-five years.

Rogers.—In Atlanta, Ga., on Friday, September 15th, Dr. William L. Rogers, aged sixty-three years.

Rubin.—In Kansas City, Mo., on Tuesday, September 19th, Dr. Barney Rubin, of San Bernardino, Cal., aged fifty-six years.

Shearer.—In Sinking Spring, Pa., on Sunday, September 24th, Dr. James Y. Shearer, aged eighty years.

Strock.—In Dyersville, Iowa, on Saturday, September 16th, Dr. David Strock, aged seventy-five years.

Thompson.—In Weber, Mass., on Saturday, September 16th, Dr. John J. Thompson, aged fifty-eight years.

Van Wert.—In New Castle, Pa., on Monday, September 18th, Dr. Floyd L. Van Wert.

Webster.—In Dayton, Ohio, on Thursday, September 21st, Dr. Frank Webster, aged sixty-two years.

Wilson.—In Bethlehem, Pa., on Tuesday, September 12th, Dr. John H. Wilson, aged eighty years.

Woofter.—In Weston, W. Va., on Thursday, September 21st, Dr. Adoniram J. Woofter, aged sixty-eight years.

THE POSTFEBRILE TREATMENT OF ANTERIOR POLIOMYELITIS.*

BY DEXTER D. ASHLEY, M. D.,
New York.

In this epidemic there has been a great cry for more efficient treatment, especially in the acute febrile stage, a cry that has been met by frantic efforts upon the part of the medical profession, calling numerous councils of its most eminent members from far and near to catalogue and systematize our armamentarium for combating this dread disease which is robbing our homes of our loved ones or leaving many maimed and crippled for life.

The laity have been led to understand that treatment was of almost no avail in the acute, convalescent, or chronic stages. It is the impression of the writer that there are not a few among the profession who are doubtful as to the efficiency of postfebrile treatment. That many so called remedies are of questionable utility, is widely believed, and rightly so; many results have been unduly accredited to therapeutic agents, which should have been credited to the natural or spontaneous recovery which is to be expected in due time, when aided by good nursing.

On the other hand, there are not a few among us who consider the efficiency of the postfebrile treatment to be surrounded with many questions. Many have very hazy understanding as to when such treatment should begin; of what it should consist at different periods; and how long each treatment should last; with the idea of attaining the greatest restoration of function in the paralyzed parts. We must admit that our armamentarium is limited.

As all are aware, the acute stage is generally conceded to extend from the onset to the subsidence of pain and tenderness, a period varying from four weeks to three months, a time sufficient to establish grave deformity. It is apparent that orthopedic measures should be instituted by the physician in attendance during this period to combat or prevent deformity. To repeat, all too frequently a tendency to deformity is started at this time that is irreparable. In this paper the writer hopes to accentuate three points:

First, the folly of no treatment in the postfebrile stages, while the patient still has pain in the nerve and the muscles are exquisitely tender.

Second, the importance of early treatment to combat deformity.

Third, the harmful effect of too much treatment, in all stages.

From our knowledge of the pathology of the disease we know that during the time immediately after subsidence of the fever, there must be given a time to absorb the hemorrhage and perivascular infiltration which have compressed vessel and nerve cells to the point of occlusion on the one hand and death on the other. It is manifest that irritation of these damaged, diseased nerve cells would be increased by a peripheral irritation or excitement.

This is the time to support the parts—to prevent stretching by weight of bed clothes that would produce drop toe, to prevent stretching of weak muscles and capsular ligaments and nerves by early sitting, standing, or assuming sprawling positions in bed resulting in the drop shoulder and the flail joint, the overextended hand or knee, the flexed knee or thigh, crooked spine, pendulous abdomen, etc.

This is the period of light diet, good nursing, warm dry packs, sheet baths, rest in a bed—firm, not too hard and not sagging—support of paralyzed parts, by nonconstricting braces, plaster of Paris, sand bags, etc.

There must be no massage, no electricity, no muscle training, no strychnine injections to irritate so long as pain and tenderness are in the muscles, pointing to an active disease still existing within the cord. At this stage any such measures are harmful in the extreme, and should not be administered until pain and tenderness have subsided, a time, as said before, varying from four weeks to three months.

In severe paralysis, especially, maintain the patient in the horizontal or inclined position for six months or longer. A Bradford or Whitman frame will permit daily excursions in the open air, when the patient may be turned over and placed at an angle to the horizontal position.

The value of prolonged recumbency is a debatable question. The patient's health should be closely observed and the horizontal or inclined position discontinued if the general health demands it. The writer is of the opinion that the disadvantages of recumbency have been exaggerated, when we consider the marked gain in weight by these patients and other children that demand the recumbent position as in treatment of the tuberculous spine.

*Read before the Poughkeepsie Medical Academy, September 25, 1916.

In the convalescent stage beginning seldom before four or six weeks and lasting for six months to two years after the acute attack, more therapeutic measures may be commanded. In severe paralysis the recumbent position is most highly recommended, as it prevents serious deformity of the spine. At this stage, if the patient assumes a position of deformity when standing, he should have a brace to enable him to walk, to support the drop shoulder, the crooked spine, etc.

This brace should support without constricting the partially paralyzed muscles. The narrow bands, denting the weak muscles, are to be condemned. Use a broad webbing or leather cuff. Great care must be exercised through frequent observations to discover and combat any tendency to deformity by application of an efficient brace, shoes or sleeping frame. As in the postfebrile stage, the limbs must not be permitted to dangle or assume positions that will stretch weakened muscles or take on contractures that would necessitate lengthening by surgical procedures to correct the deformity.

Massage at this period offers the greatest encouragement, and this massage should be given daily, or twice a day. The parent is instructed to give the massage. It is the writer's opinion that much harm is done by too long and too vigorous massage. It was the teaching of Professor Lorenz that five minutes of massage to a limb was sufficient. More was harmful, being fatiguing to the patient and breaking down rather than stimulating or building up.

To the mind of the writer the object of massage is to stimulate and bring warmth by inducing an increased blood stream to the part and emptying veins and lymphatics. It is really feeding these muscles, and they should have two meals a day. They will not thrive on one large meal or even three meals a week. The masseur whom you send to give massage to your private patients, generally spends an hour upon these patients—to earn his money—and he does more harm than good by breaking down more than can be built up, leaving the patient almost prostrated by fatigue.

In this connection Doctor Lovett, of Boston, has warned us of the ill effects of fatigue, which must be avoided if we would not harm our patients. He calls attention to the fact that muscles are generally only partially paralyzed, the proportion of partial to complete being nine to one, and these are likely to be *permanently injured* by fatigue, an eventuality that should be carefully guarded against in administering massage.

Heat is another therapeutic remedy easily applied and should accompany the bath once a day. For the same reason as massage, it stimulates the blood stream. Hot baths of gradually increasing heat—the mother or nurse holding her hand in the water as more hot water is added; hot dry packs, warm, woolen clothes, two pairs of stockings, no restricting garters, flannel binder around the waist for the pendulous abdomen. Cold inhibits muscular movement and is to be used only after a hot bath for a moment and followed by alcohol and water half and half and a vigorous rubbing or massage.

Electricity in competent hands as a test of the degree of paralysis has a value. The late Doctor Hoffa, of Berlin, taught that we should not depend upon the electrical reaction. He made an exploratory incision over the belly of the muscle in question. Pink or reddish muscles are only partially paralyzed. This is important to know when contemplating tendon transplantation. The employment of electricity is fraught with danger; if used too strong and too long at any one sitting, it makes the weakened muscles contract again and again, fatiguing and terrorizing the patient. In the mind of the writer it is a good placebo, when administered with a weak current, having the same therapeutic value as another form of massage. Its best and legitimate use will be to bring the patient for frequent regular examination once in seven to ten days in order that the doctor may better keep the child under observation and combat early any tendency to deformity. This is a hard thrust, and may not meet with approval, but such is the conviction of many competent observers.

Muscle training should be in skilled hands. Much harm has been done by the so called muscle training, where the strong muscles were made stronger and the weak muscles made weaker by too much work, the strong muscles continually increasing the deformity, as in spinal curvature. The idea is to convey an impulse from the brain to the extremity through another route by assisting in the action or movement of the partially paralyzed muscle. In competent hands, exercising great care and patience, this is one of our best therapeutic agents.

After two years, we consider the patient to have recovered as far as can be expected and he enters the chronic stage, though, after this time, should the patient have received no previous treatment as indicated above, after correcting fixed deformities, we may expect considerable development of the partially paralyzed muscles. By a thorough muscle training in some cases a marked improvement and surprising recovery after this time may be seen.

Not until after two years should any serious surgical operation be attempted, such as tendon or muscle transplantation, nerve grafting, astragalectomy, resection, arthrodesis, etc., since up to this time a valgus deformity of the feet may be developed into a resistant varus deformity by recovery of the apparently paralyzed inner muscle group—as has occurred in the writer's practice. A slight flexion of the knee by transplantation of the hamstring tendons may be converted later into genu recurvatum. Not wishing to enter into the whole field of surgery relating to these patients, I would refer you to any good book in orthopedic surgery, also to a symposium by Rogers, Ryerson, Davis, R. T. Taylor, and Wallace, in the *American Journal of Orthopedic Surgery* for July, 1916. A small reprint on the subject by the writer may be had upon request.

Altogether these cases are not so hopeless as we are led to believe upon first inspection. The writer remembers a little girl who was stricken in the epidemic of 1907. When first seen there seemed to be almost a total paralysis of the lower extremities, one side, one arm, and the other arm being partially paralyzed. The child's head had to be supported. The consensus was that it would have been a blessing had she died. Why she did not die was a won-

der. Hers was a clinical case, irregular in attendance. This patient was seen within the last three months walking without braces, with some deformity of the feet, and weak in the legs and one arm. She holds her head up like other children. She has a bad scoliosis which was marked when she was first seen. She wears a spinal brace and goes to school.

Do not be discouraged. Patient, persevering, careful work with these patients will be rewarded.

346 Lexington Avenue.

EPIDEMIC POLIOMYELITIS;

Its Nasopharyngeal Aspects,

By W. Sohier Bryant, A. M., M. D.,
New York.

The experimental work on poliomyelitis of the past six years has given abundant proof of the facts which I observed clinically in 1909-10 (New York Medical Journal, December 17, 1910) that the virus or microorganism of poliomyelitis occurs, first, on the mucous membrane of the nasopharynx and is given to other victims through the excretions of the nose and throat. There is a focal infection of the pharynx which serves as a culture plate for the organism, from which it finds its way through the lymphatics into the nervous system. After the acute stage of the disease is passed and the virus can no longer be found in the cerebrospinal fluid, it may still be observed on the mucous membrane of the nasopharynx both experimentally in monkeys, and in human cases, so that the subject may possibly become a chronic carrier. The virus is known sometimes to remain on the mucous membrane for so long as six months.

In consideration of these facts, the abortive and the carrier cases are most important. There are various types of abortive cases; my attention, as would be natural, has been directed toward the nasopharyngeal type. In this type the symptoms are nasopharyngeal inflammation of any grade whatever. Minor grades are indicated by disturbances of lymphoid tissue only, which often cannot be determined by inspection alone even with postrhinoscopy and rhinoendoscopy, but must be diagnosed by manipulation through the nose with a fine cotton applicator, with which are determined the sensitiveness and the mechanical friability of the mucosa, and with the aid of hydrogen peroxide, the character of the secretion, thereby determining the presence of pus, blood, or serum, as shown by effervescence. In 1909-10, I noted very many of these nasopharyngeal types, each of which had a certain amount of local inflammation, in communities (Hudson River Valley) where epidemic poliomyelitis existed. The number of cases of pharyngitis fluctuated in accordance with the existing number of cases of poliomyelitis. I also noted in the families of poliomyelitis patients that the other members showed nasopharyngeal irritation. Some of these showed definite symptoms of the disease, while others cleared up. Most of them were probably suffering from different degrees of poliomyelitis. I make a special point of this nasopharyngeal type, because it seems largely to have escaped attention. It should be emphasized that during epidemic poliomyelitis, the significance of nasopharyngitis is enormously enhanced. This condition suddenly becomes most important, since it may be the first symptom of a very dangerous disease. At the present writing (August) there is a noteworthy epidemic of pharyngitis associated with the epidemic of poliomyelitis in the city of New York, and an epidemic occurrence of pharyngitis has been noted in two nearby communities where poliomyelitis is prevalent. These cases are characterized by rapid onset often accompanied with much general reaction which passes away in about three days, leaving a reddened and thickened mucous membrane. It is impossible to know positively (except by laboratory inoculation) whether and how many of these cases are nasopharyngeal abortive types of poliomyelitis, but the probability is that the greater proportion of them are such. Stevens (*Intercolonial Medical Journal,* 1908) found in many instances that a slight cough preceded the onset of poliomyelitis and states that in some epidemics nasopharyngeal symptoms have been frequent. Anderson and Frost refer to sore throat and inflammation of the tonsils in some instances in their series of abortive cases. In the present epidemic, Sheffield (*Medical Record,* August 19, 1916) has reported that out of thirty-three cases, the majority began with headache and sore throat, the tonsils presenting congestion either simple or with small grayish white deposits.

Abortive cases and carriers are computed to be four to five times as many as are patients with distinct paralytic symptoms; the abortive pharyngeal cases are probably in a much greater ratio. Different writers also state that poliomyelitis occurs after or in combination with other diseases, such as whooping cough and measles, in that way escaping detection. It is safe to assert that during the present summer there has been a great number of unrecognized nasopharyngeal and other abortive and carrier cases. The unsatisfactory result of quarantine is proof of the statement. The infection of the mucous membrane of the nasopharynx is so general and so far spread that the quarantine net cannot catch the people. The whole community is under a certain amount of suspicion. The statement has been made repeatedly that the epidemic will probably end when all the persons susceptible to the disease and not completely sheltered from it have been attacked, so that there is no more human material for the disease. This sounds like an expression of fatalism: All who can have it, must have it —unless they can retire into some ideally perfect state of seclusion. But even among the apparently perfectly secluded, sporadic cases have developed in which no possibility of direct contagion existed, so that the problem of the carrier is acute.

What are we going to do with these very light nasopharyngeal and other abortive cases and carrier cases? It is through them that the disease is spread, since each is likely to be an unobserved focus of infection. Many of them are not discovered and quarantine is unfortunately practically impossible. Serum treatment is out of the question for great numbers of abortive cases and cannot, in any circumstance, disinfect the healthy carrier.

The bearing of the nasopharynx in regard to

prophylaxis, or to the relief of existing cases, or to the prevention of carrier cases has not been put to practical application. I suggest here the management of the nose and the throat with the end in view of making the pharynx a poor culture surface for the virus.

In the first place, care of the nasopharynx should be made a routine matter; the public should attend to the condition of the nose and the throat in the same manner that it attends to the care of the teeth. Health authorities and family physicians should urge regular examination of the tonsils, adenoid, and nasal passages, for the treatment of infected mucous membranes. The key to the prevention of epidemic lies in such care, not in hurried action under stress of fear after the epidemic has arrived. It is to be noted that the majority of the victims of poliomyelitis are the very little children, who, more than any other class, lack the advantages of systematic care, and who very often have obstructed noses and hypertrophied lymphoid tissue of Waldeyer's ring. These very little children are mechanically (as well as constitutionally) much more subject to the extension from the pharynx of the virus of acute poliomyelitis than are older persons, since the lymphatics of the small child are shorter but of the same calibre and consequently more easily traversed. Furthermore, in young children and even in adults, an open or partially open craniopharyngeal canal is present oftener than is generally supposed. This canal, which connects the pharynx with the cranial cavity by way of the pharyngeal and cerebral hypophyses, renders young children mechanically less resistant, as does also a constant pharyngeal pituitary easily accessible to infection. Consequently, at all times, special attention should be paid to the nasopharyngeal condition of children.

The foregoing remarks are a plea for the prevention of epidemics by the universal care of the nasopharynx. Since, however, an epidemic does exist, the great problem is to prevent its spread by persons outside of quarantine. As practical measures, I suggest, first, that during an epidemic persons coming into contact with cases of poliomyelitis, parents, physicians, nurses, even under quarantine, positively require nasopharyngeal treatment, as condition indicates, to keep them—although apparently immune—from becoming carriers by receiving the microorganism in the throat and nose and in turn disseminating it to others. Second, children in the same family of the patient should receive specially careful attention; it is my belief that there are far more secondary cases than is usually stated. Third, all cases of nasopharyngitis, however light, should be most carefully watched and their treatment undertaken without delay. Fourth, prophylaxis requires that the public at large have the nasopharynx put into proper condition; but such is the disadvantage of the occasion that treatment at this time must be restricted to application measures, as it is unwise in the presence of contagion to cause any loss of continuity of the mucous membrane of the pharynx, as would occur in adenotomy or tonsillotomy. Consequently, many cases that really need operative treatment should wait over until the epidemic has died out. Fifth, in the suspected case and in frank and abortive cases, the management of a local infection which has become a focal infection with extension and complications, is best furthered by special attention to the primary seat of infection, since the dose of the virus in extended complications is kept up from this point. That is, in poliomyelitis, the microorganism first shows itself in the nasopharynx and persists there; this is important, since the clinical history shows that the general resistance of the nervous system is greater than that of the nasopharynx, since the virus leaves the nervous system first; if this dose from the pharynx was lessened, the nervous complications would subside with proportionate speed. I offer the following comparison as an illustration: In secondary cerebrospinal meningitis from a mastoid abscess, it is obviously impossible to remove the affected nervous system, but it is possible to cut out the mastoid abscess, thereby benefiting though not necessarily curing the patient. Similarly, in poliomyelitis, it is impossible to remove the affected nervous system, but it is possible to lessen the focal infection and thereby lessen the dose of the virus which is being constantly thrown into the affected nervous system from the pharynx.

The management of a primary or focal infection is a comparatively simple matter, since it is not associated with a specially violent reaction. The local resistance is sufficient in most cases to protect the patient from further extension into the nervous system, a fact which emphasizes the importance of securing competent local resistance.

Treatment according to the foregoing outline consists of the use of sprays, application through the nose, and insufflation of powders through the nose. Sprays are used from the nose and the throat, up and back; application by applicators from below to the tonsils. Most unfortunately no specific treatment is known; it is therefore necessary to use those agents which are advantageous in nasopharyngeal infection from other organisms, of which the following is a partial list: Silver salts, colloidal and nitrate; iron salts; phenol; corrosive sublimate; essential oils; iodine solutions; kaolin; calomel; quinine sulphate; charcoal; and a number of useful proprietary articles. This treatment is similar to that best imployed in diphtheria, whose life history of local and focal infections is similar to that of poliomyelitis.

TREATMENT.

A description of the technic of one of the methods of treatment suitable for prophylaxis and for the purpose of lessening the dose after the infection may be of interest: Spray the nose with a solution of one per cent. cocaine with one in 8,000 adrenaline, to shrink the turbinates and slightly deaden sensibility. With a small cotton carrier apply hydrogen peroxide through the inferior meatus of the nose, to the back wall. If there is much effervescence of the hydrogen peroxide, make several applications until effervescence has subsided and wipe the foam from the mucous membrane. If incidentally in this application the adenoid tissue appears to be very thick, apply nitrate of silver (ten per cent., children; twenty-five per cent., adults) with a small dry applicator to the region of the adenoid and the pharyngeal pituitary, being careful not

to use enough to permit its running down the pharynx. If the adenoid tissue, on the contrary, feels smooth and thin, use a saturated aqueous solution of ferric alum (ammonioferric sulphate). For prophylaxis, repeat the treatment after four days. In cases of poliomyelitis of whatever degree, the question of repeating the application is determined on the reaction. If after twelve hours there is no reaction, repeat the treatment; if reaction is present in any considerable degree in twelve hours, let twenty-four hours elapse before repeating. In the interim, use a mild nasal spray of alkaline acetonic saline solution containing aromatics, every two to four hours.

As a detail of treatment of victims of poliomyelitis who show bad adenoids and infected tonsils, adenotomy may be indicated for the benefit of local drainage and may be most important, since the chief seat of infection is removed by this measure.

The microorganism of poliomyelitis is known to resist heat, cold, drying, glycerin, and weak phenol (0.5 per cent.). Sunlight soon kills it. In view of this fact, there is a hope of prophylaxis and treatment in phototherapy and radiotherapy; in them lies a chance of destroying or inhibiting the organism on the living mucous membrane.

In regard to epidemics in general, it may be possible that some time we shall get physicians and the public educated to realize that a bad nasopharynx is always a nuisance and a menace in the community. Perhaps, then, routine treatment of the nasopharynx will become general and we shall find that such treatment is a means of preventing epidemics, not only of poliomyelitis, but also of cerebrospinal meningitis, diphtheria, scarlet fever, influenza, and measles. This method of prevention, which is in itself a general benefit, should be urged before all other measures.

19 West Fifty-fourth Street.

INTRACRANIAL MURMUR OF LONG DURATION AND SPONTANEOUS CESSATION.*

By Frank K. Hallock, M. D.,
Cromwell, Conn.,
Medical Director, Cromwell Hall; Neurologist, Middlesex Hospital, Middletown, Conn.

The following case is of interest on account of the well marked objective character of the murmur, its peculiar behavior, its freedom from associated symptoms and the difficulty of diagnosing the nature of the abnormality. A condensed statement of the previous history is as follows:

Case. Patient, forty years old, American, married, had one child nearly fifteen years ago, of neurotic type, but now growing steady. Patient's father died of cardiac disease in middle life; mother had chronic Bright's disease, but was fairly well. Mother's sister had nervous breakdown, but recovered. Patient had one sister very highstrung. Beginning at three years of age, patient's life history was an almost uninterrupted series of illnesses and disturbing experiences. Scarcely a year had passed without some manifestation of nervous instability, the majority of attacks being a mixture of somatic and psychoneurotic elements occurring in all possible combinations, but not to the psychotic level.

At thirty years of age, the patient consulted Dr. M. Allen Starr, who pronounced the case one of hysteria with aneurysm of the basilar artery. At thirty-four years, six years ago, she came under personal observation. The fear of symptoms was eliminated, self confidence established, and an increasingly better balance had enabled her to go through subsequent upsets without mental panic.

Examination. General physical examination negative; thorax, abdomen, pelvis, blood, and blood pressure normal. Neurological examination also negative; special senses perfect, no motor or sensory symptoms. As far as the intracranial murmur was concerned, there were no special symptoms that could properly be associated with it. Mentally, patient was of high intelligence, native good sense, and reliable judgment, but with exaggerated self consciousness and very suggestible as regards personal symptoms. Altogether she was well nourished, sound organically, possessed of full nervous energy, but profoundly unstable in an autonomic sense. Throughout her life, disturbance of the vasomotor balance had been a basic factor in the great majority of the illnesses.

The importance of a serological examination was not fully appreciated when the woman was first seen six years ago, and since then with improved health she would not submit to it nor to an x ray of the head and neck. So far as the history and evidence went, there was no suspicion of specific taint, near or remote.

History of the Murmur.

From earliest recollection the patient has had a pulsating sound in the head, variously described as "pounding," "whistling," "steam escaping," etc. This description suggests tinnitus aurium, but the sounds were never referable to the ear, and all tests of the auditory apparatus were negative. As a very small child she imitated a circus acrobat hanging by her knees until her head was badly congested. The etiological significance of this act is not clear, as neither the patient nor her mother can recall whether the head sound preceded or followed the head congestion. It is certain that no great importance was attached to the performance, as the child did not know the murmur was abnormal until so informed by a physician when she was fourteen years old.

The murmur continued without change until May 11, 1909, when it suddenly stopped for three days. There was no apparent reason for its cessation nor for its sudden reappearance. This was in her thirty-third year. For the next four and a half years there was no alteration in the character of the head sound. Then ocurred one of her periodical nervous upsets, with marked digestive and vasomotor disturbance accompanied by attacks of migraine and a slight subjective change in the sound of the murmur. This change was not noticeable by the stethoscope, but was described as groaning and varying in tone. The headaches were transitory and with her general improvement the murmur was nearly the same as before.

The following spring, 1914, in her thirty-eighth year, she sailed for Naples. During the trip over and while on land the head sound continued to be well defined, as usual. The return passage was on a vessel noted for its noise and vibrations and amid the commotion of sounds and shaking the patient lost consciousness of the murmur in her head. Only once was she positive of its presence; the rest of the time she was uncertain whether it was there or not. On landing, she became fully aware that the sound had gone. Her condition at this time was excellent and her nervous system was especially stable. For some time there continued to be a slight ringing

*Read before American Neurological Association, Washington, D. C., May 8, 1916.

sensation throughout the head, but violent coughing and energetic movements did not bring back the murmur. One month later, during a delayed and disturbed menstrual period, certain head movements brought back the sound for the moment and then the ability to produce it ceased and has never returned. This was exactly two years ago.

FACTS CONCERNING THE MURMUR.

The systolic bruit can be plainly heard by stethoscope at all points on the cranium, but is most marked in the left occipital and postauricular regions. On the left side of the head the sound is loud enough to be heard by the naked ear held close but not touching the scalp. Its character, objectively, is that of a steady, pulsating, whirring, rushing sound synchronous with the pulse; subjectively, the patient states that it sometimes varies from this description and becomes bubbling, steam escaping, whistling, or frothy; when the head is held steady the sound continues to be uniform, varying slightly as the head is moved moderately in certain directions; ordinary exercises and body movements do not modify the sound to any extent; turning the head sharply to the right stops the murmur completely, both objectively and subjectively; it can also be diminished by extending the head vertically upward; rotating the head to the left or flexing it downward does not interfere with the sound.

These facts regarding the effect of head movements upon the murmur had always remained constant, but at its final disappearance, two years ago, a slight change was noticed. As previously stated, the murmur ceased after the sea voyage. A month later, during the menstrual period, the patient discovered that bending the head forward at a sharp angle and slightly to the left of the median line brought back the sound. It was of the usual character, but much fainter. Extending the head back to the normal position caused it to cease, as did also turning the head to the left. Heretofore flexion and rotation to the left had not affected the sound.

Compression of the carotids and superficial vessels of the neck did not influence the murmur. The fundi have always appeared normal and there never have been signs of cerebral pressure; no vertigo, vomiting, stupor, or loss of consciousness. Occasionally there have been transitory attacks of tinnitus aurium, described as water dropping sounds, but never any diminution of hearing nor other auditory symptoms. These attacks usually occur during vasomotor disturbance when the extremities are blue and cold and the head is congested.

DIAGNOSIS.

Any attempt to formulate a diagnosis in this case must of necessity be more or less speculative. In a review of the literature of cerebral aneurysms and of affections and anomalies of the cerebral vessels, I have not, thus far, chanced upon a report that is particularly helpful in explaining the problem before us. Von Hoffman (*Wiener klin. Wochenschrift*, 1894) and J. P. Karplus (*Arbeit a. d. Neurol. Inst. Wien*, 1902) emphasize the importance of the vasomotor factor in the production of cerebral aneurysm, and such a factor in the present case certainly is somewhat applicable. To summarize the case as well as possible, however, I may venture the following assumptions:

1. The well defined systolic bruit was due to a structural arterial abnormality existing from childhood.

2. Owing to failure of compression of the carotids to affect the murmur, the blood current involved in producing the friction sound was carried by a deep seated artery.

3. The effect of certain head movements and the anatomical course and relation of the vertebral artery to its bony bed suggest the possibility of this artery on the left side being capable of compression or other alteration of its lumen.

4. The section of artery which was the seat of the structural abnormality was not in the cervical portion of the left vertebral artery, but at or after its entrance in the cranium, or more likely in the basilar artery. This is pure conjecture.

5. This intracranial murmur would ordinarily be diagnosed as aneurysmal or its equivalent, but in addition to a constricted, dilated, or sacculated portion of artery, we can also picture the possibility of a sharply tortuous, angulated, or kinked section, either free or in relation to some bony or soft growth or projection.

6. Whatever or wherever we conceive the abnormality to be, the fact that the friction sound ceased for three days in 1909, and entirely disappeared two years ago, seems to indicate that it was not of a marked organic or serious nature and that, perhaps, along with the associated blood current, it was capable of a functional range of unusual character or degree such as would obtain in a person of chronic and profound vasomotor instability.

In these later years, with a more equalized and better balanced vascular system, it is a fair inference that there is a somewhat lessened flow of blood in the cerebral vessels and a slight diminution of the fluid volume within the cranium. This, if true, would favor cessation of the murmur. Further speculation will not avail, and autopsy alone can tell the true story.

PELVIC INFLAMMATION.*

By H. M. Armitage, M. D.,
Chester, Pa.,
Surgeon Chester Hospital.

The debate on what is and what is not inflammation, what is to be included in and what excluded from our conception of the process, proceeds merrily apace, nor does it seem likely that, until the end of the chapter, or until, following Thoma's quixotic advice, we agree to expunge the term from our vocabulary, there will be absolute agreement. In the chapter he contributes to Aschoff's *Pathologische Anatomie*, Lubarsch frankly admits that it is not one process, but a combination of processes, characterized by cell and tissue alteration, escape of cellular and fluid constituents of the blood into the tissues, and tissue growth; only when all three are associated can we

*Read before the Delaware County Medical Society of Pennsylvania, June 15, 1916.

speak of inflammation. He points out that vascular disturbances are not primary, and quotes with approval Ribbert's definition that inflammation is the sum of all those processes which, induced by various injuries to the tissues, bring about a direct action of the cells and fluids of the body upon those tissues. Ribbert, however, carries his definition so far that he includes general systemic disturbances, the results of injury among the inflammatory phenomena. Adami wholly agrees with Lubarsch that this is neither necessary nor commendable, and adheres to the definition that inflammation is the local reaction to actual or referred injury.

A foremost British pathologist, Professor Muir, takes a somewhat similar but more negative point of view. Inflammation is not a process, but a complex of processes. In a thoughtful lecture, delivered before the Harvey Society, Opie, basing himself largely upon his studies of the enzymes of the wandering cells, concludes that inflammation may be defined as the process by means of which cells and serum accumulate about an injurious substance and tend to remove or destroy it.[1] For the purposes of this article, we consider it, following Adami, as the series of local changes which constitute the reaction to injury or irritation of a part.

The causes of inflammation are microbic, traumatic, thermic, chemical, and nervous. The types of inflammation are inflammation resulting in healing by "first intention," inflammation leading directly to the formation of granulation tissue, acute fibrinous inflammation of serous surfaces, suppurative inflammation, hemorrhagic inflammation, membranous inflammation, and catarrhal inflammation.

Pelvic inflammation is usually caused by infection or trauma. The traumatic form, however, is nearly always associated with infection so that it need not be considered as a separate type.

The atria of invasion in pelvic infections are the vagina, cervix, the uterine surface, tubes, and peritoneum, each one a distinct, clean cut tissue, easily identified. When these are infected what are the routes of transmission from the primary focus? The routes of advancement are:

1. Lymph spaces.
2. The lymph vessels.
3. Veins and arteries, particularly the former by thrombophlebitis.
4. By continuity of tissue.

We will first take up the infection which occurs with parturition, and there are many different types depending upon the tissues involved in the infection. Where is the most common type? In the vagina, is the logical answer, and considering the number of lacerations which occur in the perineum and vagina, in a zone which is fearfully difficult to keep aseptic, it is a wonder that infection does not occur more frequently.

The reason it does not is because nature has prepared that field by the cofferdamming infiltration and edema which precede parturition. The field is prophylactically taken care of, and offers a high grade of resistance; therefore, the cellular tissue around the vagina, or around the perineal laceration is rarely infected.

The cervix is the next atrium of invasion, and because it is so richly supplied with lymphatics it admits infection readily. The cervix is more richly supplied with lymphatics than any other portion of the genital tract. When the infection enters the cervix, it passes through the lymphatics out into the cellular tissues of the broad ligament. If the infection is streptococcic in type, it not only passes into the lymph channels, but right on through the lymphatic glands into the circulation, and the patient dies of infection of the cellular tissue of the broad ligament, and the subperitoneal tissue behind and in front of the peritoneum; it is never in the peritoneum. When we cut into the peritoneal cavity all we see are a few flakes of lymph and no pus, and the peritoneum cuts like a piece of soggy muslin. The patient with this type of infection will inevitably succumb.

When the staphylococcus is the infecting organism, the pathology is entirely different, since the staphylococcus passes through the lymph spaces slowly, and is often arrested *in loco*, circumscribed abscesses are formed, and the patient has a localized collection of pus in the broad ligament or in the cellular tissue of the peritoneum.

On the second day, she has a chill, with a temperature of 104° or 105° F., she complains of severe pain in the abdomen, and the chill may recur the next day and the pain increase in severity. Every day or so we examine the vagina, and find the uterus fixed in a mass and immovable. The Germans say it is *Eingemauert*, which is "set in masonry." Later on there will be felt upon vaginal examination, an exquisitely tender mass pointing into the cul-de-sac, and our attention may be first called to this by the patient complaining of lancinating pain in the rectum when her bowels move.

Will the management of a case such as has been described differ from the operation on a tubal abscess? Very greatly indeed. In one we find an abscess of the cellular tissue of the broad ligament without a capsule, and in the other we have an abscess enclosed in the tube and practically encapsulated. We cannot enucleate a sac when there is none present, and we shall have our hands full if we try. There is no lining membrane present any more than in a phlegmon of the arm. Early drainage is required, and is best accomplished by opening the Douglas pouch and letting the fluid flow out through the vagina. When the infection is carried into the broad ligaments, with the enormous veins present during gestation, a thrombophlebitis may occur with the formation of septic emboli which are carried through the patient's system. We are now speaking of the type of thrombophlebitis which occurs from infection of a laceration of the cervix, after parturition or abortion, since laceration of the cervix is by no means uncommon in abortion, but infections of that type are much less frequent in abortions than in labor.

Thrombophlebitis may occur as a result of infection of the veins on the placental base. If the thrombus is not carried through the patient's system, she may recover, but only fifteen per cent. do recover as shown by statistics.

[1] Adami, *Keen's Surgery*, vi, pp. 17 *et sequentes*.

Bunn and Trendelenburg have advised operation and excision of the veins and twenty patients have been reported from their clinics, of whom thirteen died and seven recovered. The operation does not appeal to me as reasonable.

If the thrombus does enter the general circulation, the patient is doomed, and when we have seen a case we never forget the picture. It occurs with the same premonitory signs as postoperative thrombus. We have delivered a patient; the next day there is no fever, and we tell the family that everything is progressing nicely. The following day, we drop in and the temperature is probably 99.2° F., but everything else seems normal. So the patient progresses up to the fifth and even as late as the twelfth or fifteenth day. She may be eating her breakfast, or may wake up suddenly in the night with a racing heart and a pain over her heart, her liver, or kidneys, and perhaps a little blood in the urine is noticed. We hurriedly arrive, examine her from head to foot, but the only symptoms we find are the wildly pumping heart and the pain. There is no pain in the pelvis, unless the veins in the broad ligament are affected, because the thrombus in the veins of the placental base gives no pain. The uterus is freely movable and the signs of infection are negative. She will die either in this attack, or in a subsequent one in two or three days. It is one of those terrible calamities which we are powerless to combat, and occurring at a time when we think the patient has recovered. If the infection is less virulent, and occurs on the placental base, the microorganisms do not penetrate the membrane, but may be transmitted through the lymphatics into the broad ligament, causing edema and swelling of the broad ligament, and associated with chill. This type is rare because there is such a sparse lymphatic supply of the uterus above the cervicocorporeal junction.

The next variety of infection comes from the surface of the uterus. The manifestations are so varied as to enable us to differentiate them into sapremic, septic, pyemic, and gonorrheal. A great deal of controversy has arisen in the last few years as to the wisdom of curettement in these cases. Formerly it was held that curettage was the treatment in all cases of sepsis following parturition or abortion. This was an exceedingly dangerous teaching and resulted in many deaths.

Lately, as is usual, the other extreme has been reached, and some authorities believe that all these cases of sepsis should be treated expectantly. No more lurid, empty, or vicious doctrine has ever been expounded; as a matter of fact, the treatment depends entirely upon the type of infection. The sapremic form is the result of decomposition of retained products, such as blood clot, portions of placenta, or decidual membrane, and arises from the presence of saprophytes. The absorption of products of decomposition produces a condition of putrid intoxication. At the onset it may appear exceedingly grave, but it is more easily controlled than the septic forms. Sepsis is far more grave, more difficult to combat, and more destructive in its effects, than either the sapremic or gonorrheal forms. It is instigated by the streptococcus or the staphylococcus. The same germs may cause the production of pyemia.

The saprophytic form is indicated by the profuse and offensive lochia, and by finding within the uterus, upon digital examination, some decomposing material. The examination should be made very gently, since if decomposing material is not present, and the infection is due to sepsis, we do not wish to break down the barrier which has been erected by nature to prevent the infection from being picked up by the blood and lymphatics. If decomposing material is present, it should be removed. When the uterus is clear and contains no extraneous material, if we do a curettement, we shall practically seal that patient's death warrant, because we open up avenues for new absorption. If we had that type of infection in the leg, we should not go in with a curette, and scrupulously scrape away all the cofferdamming that nature had erected to guard against absorption of the infective material. If so much depends upon determining the type of infection, it is certainly worth while to attempt, with every means at our command, to find the cause in obscure cases.

The symptoms induced by septicemia will depend on the condition of the patient, the character and virulence of the infection, and the time of its introduction. Very soon, within two or three days of delivery, the patient will show an elevation of temperature which will gradually increase with evening and morning variations. Pain and tenderness in the lower abdomen are present. The pulse runs from 110 to 140, and the temperature from 101° to 107° F. A great deal of mischief can go on in the pelvis of a woman, however, with a temperature going no higher than 101°. The lochia may be absent, or thin and free. It may be odorless or have a stale, sickening smell. Persistent high temperature, pulse over 130, and absence of focalization may be taken as unfavorable signs. The cervix, vagina, and external genitalia may be swollen and covered with exudate. An early blood examination is important, not only for the purpose of determining the particular organisms, but for eliminating the possibility of other forms of infection, such as malaria and typhoid, and for determining its virulence and the antagonism or resistance of the patient as shown by the leucocytosis.

The infection is at first a limited one and is localized at the seat of injury. If, however, the microorganisms are not quickly destroyed, they and their toxins enter the lymph and blood channels, causing a general blood infection or intoxication and areas of infection at more or less distant points. The broad ligaments, the pelvic connective tissue, and Fallopian tubes are soon involved, and enlargements are felt on examination of the pelvis. This is quite different from the history of a gonorrheal infection which travels along the mucosa only.

These patients are not curetted; they are kept perfectly quiet, immobilized, absolutely at rest, with the head of the bed elevated, receiving instillation of normal salt solution by the rectum according to the method of Murphy, the vagina kept clear, and nothing at all done to the uterus. It is just about as effective to give intrauterine douches in such a

case as to direct a hose upon the lamp that set the house on fire.

Mixed vaccines or serums may be employed.

Localization is an indication for operation. The pus may be evacuated through the anterior, posterior, or lateral fornices of the vagina. When a tube or ovary is involved, the appendages should be removed. When the broad ligament and uterus are broken down, hysterectomy is indicated. In peritonitis, an incision through the posterior vaginal fornix should be made and a gauze drain inserted. The Fowler-Murphy treatment should be employed, and if the peritonitis is very extensive, other incisions may be necessary for drainage; these should be made in the flanks and lumbar regions, as indicated by the amount of pus.

GONORRHEA.

The next type of infection is the Neisserian. It comes from below, and involves first the vagina, second the urethra, third it involves the endometrium, and fourth it extends from the endometrium into the tube.

In gonorrheal salpingitis the disease travels along the mucous membrane of the endometrium, and eventually infects the lining membrane of the tubes. The broad ligaments and pelvic connective tissue are not involved, except in very rare instances, and a circumtubular abscess results in the same manner as a circumurethral abscess occurs in the male. We know, however, what a rare occurrence that is unless the patient has had instrumentation. So, while it is true that the bacillus may occasionally enter the lymph or vascular channels, causing an arthritis or endocarditis, yet this is exceptional. The moment the tube is attacked by any type of infection, except tuberculosis, it adheres to anything that it comes in contact with at its fimbriated end, and seals the end to save the peritoneum.

In the gonorrheal type of inflammation, the mucosa is bathed with pus cells, and in the submucosa are great numbers of plasma cells. Some authorities believe that the large numbers of plasma cells are pathognomic of gonorrheal inflammation. The mucous lining becomes eroded and owing to the inflammation in the submucosa, little folds of membrane are raised up at the uterine end, which retain the pus in pockets or fossæ.

Circumtubal inflammation and subsequent stricture result in exactly the same manner as circumurethral inflammation and stricture in the male. If stricture does not occur, the pus may escape through the uterus, and the tube empty itself in very much the same manner as freeing of the nasal passages occurs after a cold.

In gonorrheal salpingitis considerable time, as a rule, elapses after the endometrium is infected before the gonococcus invades the tubes and the peritoneum, and as the infection is subacute in character there is little constitutional disturbance. The patient who suffers from pain and tenderness over the lower portion of the abdomen, with a certain amount of distention and swelling, tenderness on motion, painful evacuation of the bowels, and tenderness during coition, makes it evident that there is inflammatory trouble which has more than likely reached the peritoneum by the Fallopian tubes. The normal tube is scarcely palpable. When it becomes thickened with salpingitis, it may be recognized as a more or less well defined and thickened cord, extremely sensitive to pressure.

TREATMENT.

In treating these cases it is preferable that operation should be postponed until the subsidence of the more acute attack, unless it is evident that free effusion has taken place into the peritoneal cavity, or that Douglas's pouch contains collections which are readily accessible through the vagina. In the latter case operation is usually only palliative, and an abdominal operation is usually required after the acute symptoms have subsided.

The final question to consider is what class of cases should eventually be operated in and what is the safest time after an acute infection to operate?

The chief terminal results of an infection are sterility and pain. Therefore the question of operation depends largely upon the patient herself. In some instances the patient is entirely cured. In a larger group there is more or less constant tenderness and sterility. In these cases it is the degree of pain which usually decides the question.

In a third group of cases the lesions are so pronounced and the pain and distress so severe that operative relief becomes imperative. These are the infections which leave permanent gross lesions, and in which we find present tubal and tuboovarian abscesses associated with extensive adhesions.

The question of operating for sterility alone must be answered by the patient. The results have been most successful in some cases. The patients whom operations benefit are generally not suffering with a Neisserian infection, since they rarely or never become pregnant. If we find a streptococcus or staphylococcus infection of the tube, the mucosa becomes edematous and swollen, but there is no circumtubal infiltration, and hence stricture does not take place, so that the tube becomes patulous again when the inflammation subsides. The fimbriated end remains tightly sealed, however, and the tube may slowly dilate, causing a hydrops. If the infection has been very virulent, stricture may have closed off the uterine end, and a large sacculated hydrops occurs. In many cases the fimbriated end may be freed, the edge sewed back, making an ectropion, the tube will return to normal, and the patient may become pregnant.

In that type of tube which contains pus there is only one method of treatment, namely, removal of the tube, and it may be necessary to sacrifice one or both tubes. In these cases, if an ovary is in a healthy condition it should be left, dissecting off the tube only, as it is impossible to determine what influence castration may have upon a woman's subsequent mental life. It is not necessary to remove a wedge shaped piece of the uterus when the tube is removed, any more than it is necessary to remove a wedge shaped piece of the cecum when the appendix is removed, and if we find the wall of the uterus diseased a subtotal hysterectomy should be the operation of choice.

The other infections which occur are the luetic

infections, tuberculous infection, pneumococcus infection, and colon bacillus infections.

The infections due to the colon bacillus annoy us very much. How do they occur? A child two or three years of age gets a vaginitis, due to the colon bacillus, which easily infects the tender soft young cells of the vaginal mucous membrane. The discharge is usually noticed at this time by the mother, and the child is usually brought to the doctor while the disease is still limited to the walls of the vagina. If treatment is not started at once the infection will surely pass on up through the uterus and that patient will continue to have an offensive discharge for twenty or thirty years. Pus will discharge constantly. While the infection is localized to the vagina, it can be cured.

In my experience, one drug stands out above all others in the treatment of this condition, and that is the Bulgarian lactic acid bacillus in solution and used as a vaginal douche two or three times daily. A cure is generally obtained with astonishing promptness.

In conclusion I wish to say that it is derogatory to our judgment and hazardous in the extreme to adhere strictly to radical or conservative principles in the treatment of these diseases. In the radical class are those who cut for good or ill. They obtain wonderful successes, but make terrible mistakes. The most splendid triumphs, the worst mistakes, and the saddest failures come from the radical mind. As an operator he is brilliant, relying more upon skill than upon judgment, taking desperate chances, and skimming gayly within a hair's breadth of the deadliest catastrophes.

The conservative is often a valuable factor in surgery. He is a brake on the wheel, smothers the torch of the fantastic, and snatches the mask from pretense. He attaches exaggerated importance to books and minimizes the value of new methods of communicating ideas. He is a fatuous well meaning person, and fatuity is often reason proof.

The treatment, therefore, should not be allowed to rest in the abstract realms of thought, but each disease should be met as a concrete definite entity, with that spirit which dominates, inspires, and sanctifies the science of medicine; that spirit which bases treatment upon the diseased condition caused by the infecting organism, and has for its object the prolongation of life and the mitigation of human suffering.

400 East Thirteenth Street.

CHRONIC RENAL INFARCTS,

Nephrectomy; Case Report,

By Nathaniel P. Rathbun, M. D., F. A. C. S.,
New York.

(From the Urological Department of the Brooklyn Hospital.)

Much has been written in the last few years about acute renal infarcts, more particularly since Brewer's classical description, in 1907, of the so called acute hematogenous infections of the kidney. These cases, as is well known, are hyperacute and demand prompt surgical interference in order to save life. It is also a fact that in autopsies upon patients who have died of diseases entirely independent of the urinary tract, chronic infarcts of the kidney have been often noted, which, so far as the records show, had given no symptoms during life.

A casual survey of the literature discloses no mention of chronic renal infarcts as a clinical entity. I believe it is reasonable to assume that these conditions occasionally present themselves as clinical problems whose solutions are difficult. With this idea in mind it seems fitting and proper that the following brief case history should be placed upon record:

Case. The patient, man thirty years of age, native of Russia, single, teamster by occupation, presented himself for examination and treatment, March 27, 1916. Family history negative. Personal history: Healthy childhood, never had severe illness. Five years ago, contracted gonorrhea, for which he was treated for one year and apparently cured. One and one half year ago, which was one and one half year after the supposed cure of his gonorrhea, he acquired a tendency to frequent and urgent urination, being obliged to urinate at first once at night and later two or three times at night and every hour or two by day. At this time there was no pain. One year ago, which was six months after the onset of the trouble, he began to suffer a dull pain referred to the left loin, accompanied by occasional sharp twinges referred along the course of the left ureter to the bladder. This pain had been getting progressively worse and in the last month had seriously interfered with his work. He was conscious of the lumbar pain during all his waking hours, and it was aggravated by any sudden movement or jouncing of the body. The frequency and urgency of urination had remained about the same.

Examination made at several sittings with three or four day intervals between disclosed the following: The patient was a robust, well nourished individual of the "beefy" type; mouth and throat negative; heart and lungs normal; external genitals normal; no urethral discharge; the two glass urine test showed both glasses perfectly clear; there was a soft structure in the bulbous urethra catching loosely on 26 F. bougie; prostate and vesicles normal to touch, but somewhat tender; a smear from the prostate and vesicles was free from pus cells; posterior endoscopy showed a well marked congestion of the whole posterior urethra; colliculus was enlarged, red, and granular, and bled easily; the left kidney palpable and definitely tender to palpation and deep heavy percussion; the right kidney could not be felt; bladder urine obtained by catheter was free from abnormal elements and sterile; cystoscopy showed a normal bladder, both ureter orifices normal; catheters passed readily to the kidney pelvis on either side; the kidney urine showed no abnormal elements other than a small amount of blood from the traumatism of catheterization; phthalein appeared on each side, eight minutes after intramuscular injection; von Pirquet and Wassermann tests negative. Radiographs of the entire urinary tract were negative, except that the left kidney appeared to be considerably enlarged.

As a result of instillations and topical applications the condition of the posterior urethra was much improved and the frequency of urination materially relieved, but the pain in the left loin persisted, and the patient demanded that something, if necessary, an operation, be done for his relief.

He was admitted to the Brooklyn Hospital, May 5, 1916, and an exploratory operation was performed the following day; under ether anesthesia the kidney was delivered through an incision in the loin and was found to be greatly enlarged. On palpation there were felt several hard lumps. The kidney was split, when the lumps became more apparent than before; there were four, ranging in size from a hickory nut to an English walnut, and about the consistence of a uterine fibroid. The markings and color of the medulla and cortex were apparently normal.

After consulting with several members of the staff who were present at the operation, there was doubt as to the nature of the lesion, and it was decided that nothing could be done short of nephrectomy, which did not seem warranted. The nephrotomy wound was closed with two rows of mattress sutures of plain gut, and the operation was completed in the usual manner. The patient did very well until the afternoon of the fourth day, when he had a severe secondary hemorrhage, the blood pouring through the ureter to the bladder. This was apparently controlled by a compression bandage and a large dose of morphine. The following day, the pulse was slower and there was apparently no active bleeding. At 6 o'clock on the morning of the sixth day, his pulse suddenly rose to 160, his hemoglobin went down to 20, and he presented all the signs of very severe hemorrhage. He was at once removed to the operating room and a rapid nephrectomy performed. His condition was critical for the next two days, after which he went on to an uneventful convalescence.

The specimen was sent to the laboratory for examination. Sections of the hard lumps noted at the operation showed them to consist of infarcts with definite plugging of the vessels surrounded by areas of coagulation necrosis. We might consider the possibility of these microscopic findings being incidental to his first operation. This idea, however, may be dismissed, since we know the hardened areas from which the sections were taken were in the kidney at the time of and preceding the nephrotomy.

The patient left the hospital two weeks after the nephrectomy, was sent to the country for two weeks, and on his return reported that his lumbar pain was gone, and that except for occasional discomfort which he referred along the course of the ureter, and his feeling a little weak, he was perfectly well. He considered himself cured.

It is interesting to speculate on the possible cause of this condition, but it is of course entirely speculation. As noted in the beginning of the report, there was no valvular heart lesion. We think of the teeth and tonsils as being the original seat of the trouble, and again the gonorrhea of four years ago may have been the primary focus of infection.

It occurs to the writer that this condition may account for some of the cases which we not infrequently see, in which the patient complains of lumbar and renal pain and in which the urological findings are practically negative, as they were in my case.

Given a patient presenting such a train of symptoms in whom other well recognized lesions may be excluded, I believe it is fair to consider this condition in making a diagnosis. If, added to the symptomatology, the x ray shows a large kidney which is tender to palpation and deep percussion, and all other objective findings are negative, it would be to my mind presumptive evidence that renal infarcts are the cause of the trouble. While I doubt if many cases arise which would suggest the advisability of a deliberate nephrectomy, yet the symptoms might be sufficiently severe to demand this procedure as a last resort.

67 Hanson Place, Brooklyn.

EXTRAUTERINE GESTATION.

Diagnosis and Treatment,

By Earl P. Lothrop, M. D., F. A. C. S.,
Buffalo.

Conservatism is the logical result of experience in abdominal surgery and, when associated with careful clinical and laboratory studies, favors accuracy in diagnosis. This is true in the diagnosis of extrauterine gestation and in the differential diagnosis of this abnormality from other abdominal lesions which simulate it with wonderful accuracy. It is the purpose of this paper to indicate the symptom group which excites suspicion of this condition, those signs which justify suspicion, and the pitfalls to be avoided in the final determination. The general literature has been consulted, but a résumé has not been attempted. On the contrary, the paper is suggestive rather than didactic, with illustrations taken from a group of eighty-three cases of which the writer has personal knowledge.

For convenience of description, three stages of extrauterine gestation are recognized:

1. Before rupture of the sac.
2. During or at time of rupture.
3. After rupture.

It is assumed that extrauterine gestation is primarily tubal, and that symptoms of rupture or abortion may occur at any time before the fourteenth week; that differential diagnosis between rupture and abortion is not easy, and for practical purposes hairsplitting theories should be avoided; that ovarian gestation, of which there are a few authentic records, is very rare and may safely be omitted from a paper of this character.

DIAGNOSIS BEFORE RUPTURE OF SAC.

This is rarely made for the following reasons:

1. There are no pathognomonic symptoms of this stage.

2. In the early weeks of pregnancy women rarely consult a physician unless unusual symptoms develop. The exceptions are those who are especially anxious for or afraid of conception, e. g., women who have been sterile a long time and are anxious for a child, or those seeking escape from an unwelcome pregnancy.

3. Patients subject to recurring attacks of salpingitis or appendicitis are not alarmed by an attack of pain with early pregnancy, and tradition has it that some pain is normally incident to this condition.

As before stated, there are no pathognomonic signs of an unruptured tubal gestation sac. The history of one or two skipped periods, some soreness and swelling of the breasts, one sided pain, paroxysmal in character, and uterine bleeding along with shreds of tissue may excite suspicion. If examination reveals a small tender mass in the tubal region, the diagnosis may seem more probable, but we are not justified in making a diagnosis of unruptured sac with these data alone. An accurate investigation of the patient's pelvic history should be undertaken to exclude the possibility of:

1. *Gonorrheal salpingitis.* This, to my mind, is the most frequent cause of error, the symptoms being frequently those which we have mentioned above as suspicious of extrauterine gestation. It is wise to

obtain the husband's venereal history and to examine the patient's vaginal discharge for the Neisser organism. Shreds of decidua, if found, are suggestive, and the discovery of the entire decidua is most fortunate, but rarely is this evidence available. The presence of fever is not a trustworthy differential point, because both conditions frequently have a range of temperature from 99° to 102° F.

2. *Retroverted gravid uterus,* with prolapse of an ovary and tube. I recall a history which is very much to the point: A woman, aged thirty-three years, multipara, had skipped one period; three weeks later, severe pelvic pain developed with collapse. For eleven days there were recurring attacks of pain and shock. Examination showed a retroverted uterus and a small tender mass on the left side. The tentative diagnosis of tubal gestation was made. Under anesthesia the uterus was found to be gravid, and the small tender mass to be the left ovary in prolapse. The uterus was replaced and later on the woman was delivered of a live baby.

3. *Hematosalpinx* at times may cause confusion. It is not to be differentiated from acute or chronic pyosalpinx by physical examination. Our records show three cases of hematosalpinx complicating gestation in the other tube, but none which occurred alone, although cases are reported in the literature with severe hemorrhage and shock.

Familiarity with the patient's previous pelvic condition may make the diagnosis more probable, but usually the operator should thank his intuition rather than his judgment if the diagnosis is correct. Undoubtedly this will be disputed by many practitioners, but I recall the experience of one physician who made five such positive diagnoses and in one case was right. In our series, five cases were operated in before rupture occurred, and the citation of one or two histories may be of interest.

Case I. Mrs. R., aged thirty years, married several years, had Neisser infection shortly after marriage and one attack of salpingitis. Three years previous, a uterine gestation occurred, which terminated in abortion. Had missed one period. Two weeks later was seized with violent pain in the left lower abdomen. After three days of intermittent pain, was examined and a small fusiform swelling of the left tube discovered. Temperature 98.6° F., pulse 80. Breasts were tender and uterus slightly enlarged. Operation showed left tubal sac, unruptured, and right salpingitis with sealed tube. In this case there was a definite history of gonorrhea and of salpingitis, and the only thing that one could positively say was that it looked suspicious.

Case II. Mrs. F., aged thirty-one years, nullipara, married several years; menstruation regular; gave the following history: Recurring attacks of pain in lower right abdomen for sixteen years. Three days ago, an unusually severe attack began. There was no history of a missed period or any abnormal flow. No increase of pulse or temperature. Abdominal examination revealed tenderness from McBurney's point to the symphysis. Pelvic examination revealed a small mass to the right of the uterus, which was quite tender. At operation an unruptured gravid right tube and a chronically inflamed appendix bound down by adhesions to the fimbriated end of the right tube were removed.

Case III. Mrs. M., aged thirty-five years, multipara, two living children, three miscarriages. No history of pelvic inflammation. Had missed one period. Two weeks from that time pain developed through the abdomen and rectum. Four weeks from the missed period a similar attack occurred and flowing began. Examination showed slight breast signs and slightly enlarged uterus; no mass nor fluctuation in the pelvis, but general tenderness. Curettage and vaginal incision revealed a right tubal sac, unruptured.

In our series of unruptured tubal gestation sacs, I am frank to admit that the diagnoses seemed to be most probable, and in these five cases operation justified the suspicion, but there have been others whose records are not at hand, in which the histories were just as positive and aroused an equal suspicion, in which the diagnoses were incorrect.

DIAGNOSIS AT TIME OF RUPTURE.

Ordinarily there is no suspicion of this abnormality until the time of rupture, and the accuracy of diagnosis at this time seems to depend upon the severity of the symptoms rather than upon the grouping of the symptoms, e. g., in our series only eight were identified in the first four days, eighteen in the first ten days, while sixty-five were between fourteen and 365 days. When rupture occurs with great loss of blood and rapid development of anemia, the diagnosis is much more suggestive than when the rupture occurs with but small loss of blood. The character of the pain, while frequently excruciating, is not unlike that observed in other types of acute abdominal disturbance, e. g., ovarian cyst with twisted pedicle, gonorrheal salpingitis, hematosalpinx, ruptured ovarian hematoma, ruptured varicose broad ligament veins, etc., but the fact that its onset is sudden, that it is paroxysmal in character, and often associated with blanching of the patient and evidences of shock, should be regarded as valuable evidence when associated with uterine discharge and a history of pregnancy. When rupture occurs with great loss of blood and pronounced shock, pelvic examination is frequently of little value. There is no mass to be felt, and while the blood is fluid there is but slight evidence of bogginess in the cul-de-sac. In a small percentage of cases pain and hemorrhage are absent. In fourteen of our cases vaginal bleeding was the first abnormal symptom, and pain had not occurred up to the time of operation. In these cases pelvic tenderness was present, but no real pain. In fifteen there was a history of pain without uterine bleeding. In one there was a history of flowing beginning at a regular period without pain. In fifty-three there was a fairly typical history of skipped menses, signs of pregnancy, development of pain, and vaginal discharge. It would seem that the symptoms of extrauterine gestation are not always typical, but it is fair to say that at time of rupture the symptoms are pronounced enough to excite a very strong suspicion which in the great majority of cases the history and examination will verify.

The number of patients in our series seen in the state of collapse was ten, and in passing it might be noted that the severity of the prostration or shock is not always in proportion to the amount of blood lost as Waldo (*Transactions of Am. Assn. of Obstrs. and Gyn.*, XXIII) has shown. There seems to be more shock and prostration in the rupture of an interstitial, and less shock in tubal abortion. Witness, Mrs. S., twenty-seven years, nullipara, with a history of skipping two periods, seized with severe abdominal pain without uterine discharge. Brought into hospital very pale, pulse weak, rapid; subnormal temperature, slight enlargement of uterus, with

mass in left tube near uterine end. At time of operation, a ruptured interstitial gestation sac was discovered, with a small amount of blood in the abdomen.

Another case was that of Mrs. C., aged twenty-nine years, nullipara, skipped two menstrual periods; twenty days later, at 7 p. m., was seized with sharp pain in lower right abdomen. Vaginal examination elicited pelvic tenderness, but no mass. At 8.15 p. m. became blanched, semiconscious, and almost pulseless. Vaginal examination showed no fullness in the cul-de-sac. After salt solution and morphine, was operated on at 11 p. m., and the abdomen was found full of blood with a ruptured sac in the middle of the right tube.

The degree of shock in these two cases was very similar. The amount of blanching was obviously greater in the latter case. That shock and apparent exsanguination alone do not indicate a ruptured extrauterine sac is illustrated by the history of Miss B., twenty-eight years old, nullipara, whose past history was unimportant save for an attack of tonsillitis two weeks previously. Menses regular and period just due; seized with excruciating lower abdominal pain and vomiting; began to flow; six hours later, entered hospital, exsanguinated; pulse weak and thready; lower abdomen to umbilicus dull on percussion; upper abdomen tympanitic. Bimanual examination revealed fluctuation—no breast symptoms. Operation revealed abdomen full of blood and a large ruptured ovarian hematoma.

Many patients with the onset of pain have nausea, vomiting, upper abdominal distention, which they mistake for an attack of indigestion, and our histories show a number treated for supposed indigestion with recurring attacks. Unquestionably some patients with extrauterine gestation, with slight pain and slow bleeding, discharge the fetus and membranes into the abdomen and make a spontaneous recovery, or else the only suspicious sign the examiner finds is a small hematocele which may disappear without recurrence of symptoms.

Proof of this statement will be found in the operation records of any hospital. If the fetal sac ruptures, death of the fetus will ensue and the remains of gestation may be found accidentally when operating for some other condition. The following case is illustrative:

Case V. Mrs. B., aged thirty-nine years, one child, two miscarriages. Never been well since birth of child seven years ago, complained of constant pelvic pain, backache, and attack of right sided pelvic pain. Examination showed lacerated perineum, retroversion, and tender appendages. Operation revealed chronic appendicitis and right salpingitis. At the fimbriated end of the left tube was evidence of an old abortion. Patient could not give data from which the time of occurrence could be computed.

Case VI. Mrs. G., aged thirty-eight years, multipara, three children, two miscarriages. Ill nine months; pain in right lower abdomen, attacks of flowing sometimes lasting six weeks, at other times regular menstruation; four distinct attacks of indigestion; pain in the right side; nausea; fever. Examination showed large boggy mass in cul-de-sac. Operation comprised cul-de-sac incision, release of large amount of dark grumous bloody material with some clots. Section: Hematoma of left tube and ovary, which proved to be an old tubal gestation sac, right salpingitis, and ovarian cyst.

In reviewing histories we observe that most cases present suggestive symptoms at the time of rupture, but only a small proportion are diagnosed with their first attack of pain, most of them having had several attacks of pain and persistent symptoms for many days. In support of this statement, the number of days elapsing between the time of onset of pain and the date of operation are offered: In sixty-one cases this could be determined with relative accuracy and varied from one to 365 days. Thirty-seven were operated on within thirty days; fifteen between thirty and sixty days; five between sixty and 100 days; one, 150 days; one, 180 days; one, 270 days; and one, 365 days. This statement, in view of the fact that only ten of the cases of our series were seen in a state of collapse, would indicate that in nearly every case there is sufficient time for careful study of the history and present condition before making a diagnosis. There are some points in the diagnosis of tubal gestation at the time of rupture which our records suggest. Except in cases of marked shock and clear history, the diagnosis at this time must in general depend upon the history of supposed pregnancy, sudden onset of pain, some degree of shock, uterine bleeding, passage of decidua, and absence of fetus in the discharge. The two latter symptoms are rarely verified. It is not possible to determine the portion of the tube in which the pregnancy is situated or whether tubal abortion has occurred. The possibility of salpingitis must never be forgotten.

DIAGNOSIS AFTER RUPTURE.

After hemorrhage ceases, a tumor usually forms on one side of or back of the uterus. The patient recovers from shock and may exhibit a variety of symptoms, basically those due to presence of a foreign body in the peritoneum or broad ligament. If the former, signs of peritonitis, local or general, may appear with distended intestines walling it off above. The tumor may push the uterus forward, crowding the bladder and rectum. Pain, shock, and hemorrhage may recur from time to time, with increase of size of the tumor, or fatal syncope may supervene. If the bleeding has taken place in the broad ligament, the symptoms are less severe, and peritonitis is generally absent. At this time diagnosis is usually plain. The history of pregnancy, pain, shock, flowing, development of tumor, and exsanguination of the patient can scarcely be confounded with other conditions. If untreated, a condition of invalidism may result, or death from hemorrhage or septic peritonitis may occur. Sometimes after rupture, the fetus continues to grow, having either the original site of the placenta for its source of blood, or in cases of complete detachment, finding another point for placental implantation favorable for development.

In our group, two fetuses were alive at time of operation; one a few weeks old with placental attachment in the fimbriated end of the tube, the other four and one half months old, the tube ruptured and the placenta finally attached to the posterior surface of the broad ligament.

If the fetal sac ruptures, the fetus dies and, if small, may be absorbed; otherwise, unless removed by operation, it becomes encysted, either to remain

as a lithopedion or to undergo suppuration and be discharged into the bladder, rectum, or vagina.

Diagnosis of the last named condition may not be clear if a complete history is not obtained, and may be made only when parts of the fetus are discovered in the discharge. Lithopedia may be palpable or the history suggestive, but more often they are first discovered after the abdomen is opened. In the present day x ray examination will help in the diagnosis. When the fetus is free in the abdomen and living, the diagnosis seems to offer but little difficulty. The fetus can sometimes be felt through the abdominal wall. The uterus is enlarged, but not in proportion to the duration of pregnancy. Any doubt as to its size can be settled with a sound. The breast symptoms are normal, the uterine discharge ceases, fetal heart tones and placental bruit appear. The usual course of pregnancy follows until labor begins, when pains without uterine discharge occur and the fetus dies. The only condition which may simulate this, that I know of, is double ovarian cyst crowded together behind the uterus. With this there are symptoms of pregnancy save fetal heart and placental bruit. We mistook one such case for a gravid uterus with a dead fetus.

Before concluding this section of my paper, may I rehearse some other statistical facts disclosed by the analysis of eighty-three cases? These are not absolutely pertinent to the subject, but are offered as a matter of interest. The ages of our patients range from twenty-one to forty-one years, fifty-four occurring betwen the ages of twenty-one and thirty-six, nineteen between the ages of thirty-six and forty-one years, and in ten cases the age was not correctly given. We found gestation going on in the right tube in forty-three cases and in the left in forty. The number of tubal abortions was fifteen; unruptured five. Of the ruptures, two were interstitial. Fifty-nine occurred in the middle of the tube; two at the fimbriated end. In our series of eighty-three cases there was one death from shock a few hours after operation. One patient died two years later from obstructive ileus. Carefully gathered statistics by various authors seem to show that tubal abortion is the usual result, and that many cases which we have been accustomed to classify as rupture of the tube proper, are really tubal abortion. It would seem wise to adopt Williams's classification of extratubular and intratubular rupture and abandon the term "tubal abortion." Two were a combination of tube and ovary which might have been tubal or ovarian, but could not be classified properly from macroscopic study. In fifteen cases the other tube was diseased. In twenty-one there was a chronic appendicitis. Three cases had been operated in for tubal gestation on the other side, some time previous, one three months, one four months, and one three years. One patient gave a history of an attack of pain six months previous, with tenderness in the abdomen relieved by a discharge of pus into the rectum, forty-two days before operation without symptoms of pregnancy, was taken suddenly with severe pelvic pain lasting for several hours, tenderness which continued for two weeks, then a second attack of pain in the same place. Examination showed a mass to the right of the uterus. Operation found a ruptured tubal gestation sac and an appendix bound down with adhesions to the rectum.

SUMMARY.

There are no pathognomonic signs of an unruptured tubal gestation sac. Such diagnoses are rarely confirmed by operation. At the time of rupture, there is usually sudden pain followed by flowing; a feeling of faintness or callapse may accompany these symptoms. After rupture, the history of repeated attacks, together with the finding of a pelvic tumor may guide us correctly. In all cases the possibility of gonorrheal salpingitis should be carefully considered.

TREATMENT.

When the most probable diagnosis is unruptured extrauterine gestation, abdominal section is indicated. Bandler suggests curettement and examination through a vaginal opening, a procedure found most useful in practice, but the removal of the tube through this incision is not always easy or satisfactory. When rupture occurs, unless the patient is in extreme collapse, immediate operation is demanded. With extreme collapse, at this time it is wise to give morphine and salt solution and wait until the patient recovers from shock. With great pallor and anemia, I prefer not to wait very long, but think it wise to open the abdomen, clamp off the bleeding tube, and then wait for salt solution to raise the blood pressure to the safety point. It is a noticeable fact that the pulse rate will improve under anesthesia in cases showing marked shock, and while it is appreciated that the hemorrhage differs from the ordinary postoperative hemorrhage due to broken or slipped ligature, yet we have never regretted opening and placing a clamp on the bleeding tube. Cases with mild symptoms and slow bleeding with the development of hematocele, when seen late, may be treated conservatively. Some subside without recurrence of symptoms; some become infected and are drained later. Such cases can be kept under observation and operation be performed later if there is a recurrence of hemorrhage. Undoubtedly many of these cases occur which are never recognized as such, making either spontaneous recoveries or later developing into pelvic abscesses. It is not my purpose to urge this method of treatment, but we all meet with patients who refuse operation and this termination should be remembered. When broad ligament hemorrhage occurs, two methods are applicable, puncture, evacuation, and packing, or section with ligation of the vessels and complete removal of tube and ovary. The latter method is the more surgical, although attended by much bleeding at the time of operation.

If a viable fetus is discovered, in either the broad ligament or peritoneal cavity, there is often a question whether to remove it at once or wait until after its death. This seems to depend somewhat upon the stage of development and the position of the fetus. A few have been delivered at a viable period and lived, but the prognosis is not good. Defective nutrition and cramped quarters do not favor normal development. Although many

authors favor waiting until the child is dead and the fluids are absorbed, it seems that most men favor delivery *per abdomen* about the eighth month. The removal of the placenta offers difficulties.

One of our cases went to maturity and was operated in 365 days from date of onset of pain. The removal of the fetus was easy, but the placenta was so firmly attached to the intestine that complete removal was extremely difficult and the patient had many painful adhesions afterward with recurring obstructions, one of which finally caused her death.

In the ordinary cases the tube should be removed, the free blood aspirated, and such blood clots, as can be safely separated, removed. When much blood clot is found attached to the small intestine, obstruction must be thought of, and when it occurs, immediate enterostomy be performed. In one of our cases three obstructions developed after the second extrauterine impregnation, and were finally relieved by short circuiting the proximal portion of the ileum into the sigmoid. The question as to whether double salpingectomy should be done, is still an open one. There seems to be some connection between salpingitis and extrauterine impregnation, but the question is not settled.

In conclusion, let me urge that every case of supposed pregnancy in which develops sudden pain, flowing, or shock, be considered extrauterine until proved otherwise. That these cases are frequent needs no emphasis; that they are often overlooked is evident. Ever present suspicion of the condition would lead to early recognition and proper treatment.

STATUS LYMPHATICUS.*

A Report of Two Cases,

By William Ledlie Culbert, M. D.,
New York.

One of the most tragic experiences in surgery is the unexpected loss of a patient on the operating table from thymus enlargement, or from what is usually called, for want of a more definite term, status lymphaticus. To recall some of the conditions to mind, I cannot do better than to quote from Warthin's classic article in Osler's *Modern Medicine*. He says:

> It is of course evident that the condition of thymic death is that classed by many writers as the chief feature of the status lymphaticus. It is, however, a question whether the latter represents a definite primary pathological entity; it is much more probable that the clinical and pathological features usually regarded as characteristic of lymphatism constitute a cachectic complex, secondary, perhaps, to a number of primary morbid processes, such as syphilis, rhachitis, some latent infection, autointoxication, etc., that are characterized by an excessive demand upon the lymphoid and myeloid tissues of the body. At a certain stage in the process the lymph nodes may be enlarged, and it is to this stage that the term status lymphaticus is usually applied.
>
> The thymic enlargement is most probably to be regarded as a purely compensatory condition, secondary to some primary lymphotoxic or myelotoxic process. The sudden death in status lymphaticus is dependent primarily and wholly upon the thymic enlargement, and the latter condition becomes therefore the most important feature clinically. Moreover, thymic enlargement, leading to thymic death, may exist without any of the other clinical features ascribed to status lymphaticus. Nevertheless, the latter term serves a good purpose in designating the cachectic complex of thymic enlargement associated with adenoids, enlarged tonsils, enlargement of the superficial lymph glands, rhachitis, etc.

*Read before the New York County Medical Society at its March meeting, 1916.

Of the two patients whose case histories I will narrate the first was the son of a physician, in a neighboring town; the second was a ward patient in the service of Doctor Rae at the Manhattan Eye, Ear, and Throat Hospital. Both these patients had well marked general tuberculous adenitis; in addition, the first had an enlarged thymus, which was undoubtedly the cause of his death; the second also had an enlarged thymus.

Case I. W. F. L., seven years of age, born in the United States, the youngest of seven children, all healthy. Parents, both living, well, and strong. There was no family history of tuberculosis or chronic disease. He was first brought to my office by his father on June 6, 1915, with the history that he had always been well and able to hold his own with his playmates in their games and contests. Four years before, when he was three years old, the glands of his neck became swollen without apparent cause, but subsided in due course and remained quiescent until four months previous to consulting me, when he had an attack of tonsillitis, at which time the glands of the neck, especially on the right side, again became swollen, the condition continuing and progressing up to the time of the visit.

The child was a mouth breather and presented a large mass, the size of his fist, on the right side of the neck, the centre fluctuating, and he looked pale and anemic. Examination of the nose revealed nothing abnormal. The tonsils, however, were unhealthy looking and were much enlarged, meeting in the middle line when the tongue was depressed; the crypts were large and gaping. A large adenoid mass was present. A chest examination showed the heart and lungs to be apparently normal, but I did not like the child's appearance and did not wish to operate until he was in better condition; so advised that he be taken back to his home, kept out of school, allowed to play in the open air, and made to lead a simple hygienic life. I further directed that a little vaseline be instilled in his nose several times a day, that he receive proper breathing exercises, take a tonic which was prescribed, and report back to me in a couple of weeks.

The father had desired to have the boy's tonsils removed as soon as possible, but on account of the cervical adenitis I was unwilling to perform the operation for fear of setting up a more acute condition. On June 16th, ten days later, the father appeared again at my office without previous notice, saying that the boy was much better and that he would like to have him operated on, that day. The boy's general appearance was improved, and the tonsils had subsided slightly, but the lump in the neck had remained unchanged, except that the centre was more fluctuating. Consequently, it was decided to dissect out the glands on that side, and to take care of the tonsils and adenoids later.

The boy was admitted into the hospital and walked into the operating room, climbed on the table without assistance, and took the anesthetic quietly. This was administered by an expert anesthetist, very little ether being given. I proceeded at once to dissect out the glands of the right side, through the usual incision. Everything progressed rapidly and satisfactorily. The glands formed a large mass, involving the deep vessels of the neck as well as the sternomastoid muscle and the spinal accessory nerve. Two large ones were broken down and were filled with caseous pus and necrotic tissue. I had finished dissecting around the

deep vessels of the neck and was just about liberating the spinal accessory nerve when the father, who was sitting near the child's head, remarked: "How finely he is taking his anesthetic; his pulse is splendid." Less than two minutes later, the anesthetist noticed that the child was not breathing, and the pulse could not be felt.

Hypodermics of strychnine and camphor were given, also a saline enema, artificial respiration and the pulmotor were brought into use, but all were without avail. The child died within forty minutes of the beginning of the anesthesia.

Recognizing that there was something unusual in the child's sudden death, which suggested a thymic death, I obtained the father's permission and the body was taken to the laboratory, where Doctor Law made the radiograph. Quickly developing the plate, he recognized the presence of an enlarged thymus. I then asked the father's permission for an autopsy. This being granted, and our pathologist being away at the time, the body was taken to the morgue and, again with Doctor Law's assistance, the breast plate was cut away, revealing a large mass spreading over the anterior surface of the heart. This was carefully dissected up from below and was easily removed, except at and above the sternal notch. The gland measured twelve cm. in length, 4.5 cm. in width, and 2.5 cm. in thickness.

The second case has a rather long history, covering a period of several months and a stay in several hospitals. For this history and physical examination I am indebted to Dr. R. L. Hutton, attending physician to the Manhattan Eye, Ear, and Throat Hospital.

Case II. S. A., five years of age, of Turkish parentage; both parents and five other children living and well. Family history negative as regards tuberculosis or other disease. The child had had no illness prior to May, 1915, when the parents noticed a small lump on each side of the neck, which seemed to gradually increase in size, but were never painful, nor did they break down or discharge. Later, smaller lumps were noticed in both axillæ and groins. In the same month, the child caught scarlet fever, and was removed to Willard Parker Hospital on the 22nd. The scarlet fever was complicated by otitis media, adenitis, and nephritis, necessitating a stay in the hospital until October 3rd, practically five months.

Two days later, the child was admitted to St. Luke's Hospital and remained there from October 6 to 25, 1915. Doctor Hutton obtained for me a full history from the St. Luke records, but I mention only the most salient points, and draw attention especially to Doctor Gould's physical examination, which I cite later by his permission.

The chief features observed while in St. Luke's were the general glandular enlargement (especially marked in the cervical and axillary groups), discharging ear, nasal discharge, and an irregular fever, running up as high as 103.2° F. There was little anemia; hemoglobin, seventy per cent. The red blood count was 4,500,000; white cell count, 11,500 to 13,500; with moderate lymphocytosis, forty and forty-two per cent., small and large lymphocytes together. There was pus in the urine, but no casts. "Physical examination of the chest showed slight dullness and harsh breath sounds posteriorly in both suprascapular regions; elsewhere normal resonance, voice and breath sounds. Over the upper portion of the sternum and for about one half inch on either side of it, there was dullness (mediastinal?)." The liver and spleen were enlarged. The ear examinations showed chronic suppuration with a large polypus and granulation tissue filling the fundus of the canal.

During the child's stay in the hospital, his condition improved and there was little fever at the time of his discharge. When he was first admitted to St. Luke's, one of the larger discrete glands in the right axilla was excised and examined. The interior of the gland was found to be caseous, and the pathological report was tuberculosis. Wassermann and von Pirquet tests were negative.

On November 5, 1915, about ten days after leaving St. Luke's Hospital, he was brought to the clinic of the Manhattan Eye, Ear, and Throat Hospital, for treatment of his left ear and the glands of the neck, and was admitted to the hospital, under my care. The symptoms presented then were similar to those in St. Luke's examination, detailed above. The ear discharge was perhaps more profuse, and the parents stated that the glands of the neck were more enlarged. There was a profuse purulent discharge from the nose, and the tonsils also were enlarged. The temperature on admission was 101.6° F., during the child's stay in the hospital, covering a period of a little over four weeks, the temperature continually rose and fell, varying from 99.2° to 104.4° F. The Wassermann was negative. Cultures from the nose and throat showed Staphylococcus albus; no Klebs Loeffler were found. The blood examinations and blood counts, of which a number were made, showed practically the same condition as at St. Luke's. The urine examination showed a decided amount of pus. One additional feature calls for attention —the presence of two badly decayed teeth in the left lower jaw.

An x ray of the chest gave a shadow of an enlarged thymus.

At both the Willard Parker and St. Luke's Hospital a radical mastoid operation was advised, but was not performed on account of pus in the urine. At the Manhattan, a radical mastoid was also advised, as well as the removal of the then much more inflamed cervical glands, but neither was done, not only on account of the pyuria, but because of the enlarged thymus which the radiograph indicated.

On December 4, 1915, the child was removed from the Manhattan to the Sea Breeze Hospital.

In conclusion, I would like to draw attention to the importance of:

1. A thorough physical examination of all children who present themselves for operation, especially those for removal of adenoids and tonsils; more particularly when they show any deviation from the normal should we look all over the body for enlarged glands, bone deformities characteristic of rhachitis, and areas of sternal dullness. Pribram, of Prag, draws special attention to enlarged papillæ at the base of the tongue and an omega shaped epiglottis.

2. If any stigmata are present to make us suspect an enlarged thymus, operation should be refused, or, at least, deferred until a full laboratory investigation can be made, including, of course, skiagraphs.

CYSTOSCOPIC RECTOVESICAL TRANSILLUMINATION.

By P. S. Pelouze, M. D.,
Philadelphia,
Cystoscopist, Genitourinary Department, Jefferson Medical College Hospital.

Digital examination of subvesical structures per rectum is at best uncertain. The examining finger is a short instrument and a pathological condition must be placed low down to be thus discovered; also, it must be distinctly palpable as to contour and consistence to give information of certainty. To decide beyond a doubt that we are dealing with disease, is at times impossible, and anything that aids in diagnosis in this region of more or less uncertainty has a distinct value. For this reason I am led to describe

the application I have made of the old method, transillumination, to these structures.

If we insert the cystoscope into the bladder, dilate the viscus with water, introduce an electric bulb into the rectum, and turn out the cystoscopic light, we find it possible to transilluminate the intervening structures. So thoroughly can this be done that the tiny bloodvessels of the base of the bladder are distinctly seen, and changes in tissue thickness and density can be accurately determined, and the ureter followed for a little distance. While I have not had the opportunity to study such a case since first using the method, I feel perfectly sure that stones in the lower end of the ureter could be distinctly seen.

Owing to the small field of distinct vision offered by the cystoscope, and the close proximity of the rectal light, a large surface cannot be observed at one time, but by moving the rectal light in various directions and following the illuminated portion with the cystoscope, the size and mobility of the rectum permit of a study of the entire base of the bladder and well up on the posterior wall.

In the normal bladder, the light becomes visible in the median line about 1.5 cm. behind the so called urethral uvula, and can be seen as it passes up along the posterior bladder wall. When moved laterally,

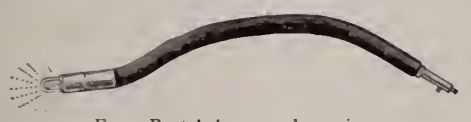

FIG.—Rectal lamp and carrier.

it becomes dim and disappears behind the ampulla and seminal vesicle; if held directly under the ureteral orifice, the distinct widening of an ellipse of intense light can be seen during the expulsion of urine, the surrounding muscle fibres and ureteral wall showing much greater light obstruction.

For the purpose I have had made a curved shaft for carrying a large transillumination lamp. This curve was found necessary because the straight shaft not only restricted lateral motion but pushed too sharply into the base of the bladder. The lamp gives a very brilliant light, and, being surrounded by an air chamber, there is no danger of producing a burn.

The technic is extremely simple, offering no difficulty whatever to one moderately skilled in the use of the cystoscope. With a little practice, it is hardly necessary to light the cystoscopic lamp for purposes of orientation, but this can easily be done from time to time more accurately to locate a given area.

Obviously the real value of this procedure is in the determination of infiltrations of tissue from vesical, prostatic, or rectal gowths, and the diagnosis of stones in the lower end of the ureter. Whether it will be of much value in conditions involving the seminal vesicles is a question, as these organs vary so much in shape and size that we hesitate to diagnose inflammatory changes here from shadows alone. A perivesiculitis, however, passing toward the median line would give a shadow so very different from that of its fellow as to confirm other findings, or, if the inflammation is bilateral, the obliterating or narrowing of the normal illumination in the median line will be of value.

1831 CHESTNUT STREET.

OBSTETRICAL ABDOMINAL HYSTEROTOMY,

With a Report of Twelve Cases,

BY ALFRED M. HELLMAN, B. A., M. D., F. A. C. S.,
New York,

Adjunct Obstetrician and Gynecologist, Lebanon Hospital; Attending Gynecologist, German Hospital Dispensary.

Although it was eighty-nine years ago that Richmond performed the first Cæsarean section in America, the value of this procedure seems still to be undefined in the minds of some. Certainly the laity is still of the opinion that it is the gravest of obstetrical procedures. Controversy of late has led me to believe that every one with experience in this line should report his results, so that the value and safety of the operation may be made clear to the practitioner and through him to the laity. My twelve cases were as follows:

Four were for disproportion between head and pelvis, at term; all four mothers and four children made uneventful recoveries. One case was for labor complicated by ventrosuspension and a transverse position of the child; the mother was out of bed on the eleventh day, and the child did perfectly well. Three cases were for placenta prævia at or close to term; mothers and babies made uneventful recoveries. One case was for congenital occlusion of the vagina with slightly contracted pelvis; I have reported it elsewhere—the mother and child did well. Two Cæsarean sections were for eclampsia, at term; both mothers died of continued convulsions within twelve hours of the operation, but the babies did splendidly. These maternal deaths cannot be ascribed to the operation. The Cæsarean section cannot be called the cause of death any more than the digitalis administered to the failing heart in pneumonia can be called the cause of death in that dread disease. One hysterotomy was for eclampsia at six and a half months; the child breathed for six hours and then expired, while the mother made an uneventful recovery.

In only two of the cases were there any complicating features. In one of those operated in for disproportion, after the woman had been in labor thirty-six hours with membranes ruptured, there was considerable fever with pains in the lower abdomen, both lasting for two weeks. But at the end of the third week, the patient returned to her home in perfect health. The patient with congenital occlusion of the vagina, after reaching home, passed three of the chromic sutures used to close the abdominal fascia through a small opening in the abdominal wall.

The technic is simple, provided always that perfect asepsis and sufficient assistance are to be had. The first two cases were operated in by the large incision above and below the umbilicus. In all other cases the method described by Davis was followed. I give the technic in detail because I think this method gives the best results. The vagina is wiped out with tincture of iodine full strength, and the patient catheterized. The entire abdomen and lower part of the chest are covered with iodine, and sheets and towels are spread as in any laparotomy, and just when ready to operate, pituitrin, one c.c., and aseptic ergot, one c. c., are given hypodermically. An incision is made, starting at the upper edge of the umbilicus extending upward along the midabdominal line for about three inches. When once we are in the abdominal cavity, the intestines are packed away rapidly and walled off from the uterus with sterile moist pads. A three inch incision is now made at the very top of the uterus, midway between the inner ends of the tubes. The membranes or placenta are torn through with the finger and the baby delivered, feet first. The cord is clamped and cut and the baby

handed to an assistant, who stands ready to receive and revive it, because these infants are regularly born in a state of acapnia. Up to this step three minute or less has been consumed and we may now take our time. Either end of the uterine wound is grasped with a single pronged bullet forceps and held taut by the first assistant. The operator then passes his hand into the uterine cavity and removes the placenta and membranes entire. Now we are ready for suturing. A No. 2 plain catgut running suture is used to sew muscle to muscle of the cut uterine edge, care being taken to avoid the endometrial lining and peritoneal covering of the uterus. Then the peritoneum of the uterus is sutured with a No. 1 or 2 running twenty day chromic suture. The corners are reinforced by one or two interrupted sutures. All pads are removed and the abdominal wall is sutured in layers. Less than thirty minutes will have been needed, and the patient will be in perfect condition and have suffered a minimum loss of blood.

This method is easily the best so far devised. It has distinct advantages over other and older methods. Everything is plainly in view, the incision is made into the high part of the uterus where in succeeding labors there will be least strain, and there is no possibility of adhesions between uterine and abdominal scar. The low incision, extraperitoneal or transperitoneal presents many more technical difficulties; the exposure is not as good, the bladder and ureters may be injured. None of these difficulties are encountered in the high incision. An infected case where a laparotomy must be done is the only indication for the extraperitoneal incision.

As for the vaginal Cæsarean operation, the difficulties are still greater. In 1906, Palmer Findley reached the following conclusions:

1. It takes less time to do an abdominal than a vaginal Cæsarean section.
2. Greater cleanliness is assured.
3. Abdominal incision is wholly under control of the operator.
4. Patient can be sterilized, if needed. Tumors, etc., can be removed.
5. More likely to obtain a viable fetus.
6. Rupture of uterus more likely if low incision is used than high.
7. Bladder and ureters will not be injured by high incision.

I can see no reason to withdraw any of these conclusions; I should simply like to add that abdominal Cæsarean section returns the parts much more nearly as they were before than does the vaginal. The convalescence is less painful and much more likely to be smooth.

The prognosis is in general good, especially good when it is the method decided upon before labor sets in, and when no vaginal examinations are made late in pregnancy and no trial of labor is allowed. Obviously, the absolute prognosis in any particular case must depend on the condition for which the Cæsarean section is performed, and above all, "the mortality of the section in general," as Reynolds puts it, "is proportionate to the amount of labor that has been endured before its performance."

When considering the indications for Cæsarean section, the need of individualization is as imperative as in any field of medicine or surgery. When we say such and such is an indication for Cæsarean section, we mean, first and above all, that in the condition mentioned section must be given due consideration as a possible means of giving the mother a painless childbirth with speedy convalescence, and we must hope for a living child. Hence we consider as indications for Cæsarean section:

1. Relative disproportion between fetus and pelvis.
   a. Contracted or deformed pelvis.
   b. Monster or overgrowth of fetus (dead or alive).
2. Tumors obstructing labor.
   a. Of the bony pelvis, as in exostosis.
   b. Of the uterus, as fibroids or cancer.
   c. Of the ovary, as cyst or tumor.
   d. Of the sigmoid or rectum.
   e. Displaced kidney acting as a tumor.
3. Placenta prævia, especially if central at term. Under this head may be included accidental hemorrhage.
4. Eclampsia—to empty the uterus rapidly without much shock.
5. Certain malpositions, as impacted face or cross presentations. This latter is frequent after ventrosuspension.
6. Deformities of uterus and vagina.
   a. Atresia vaginæ.
   b. Double uterus.
7. Severe cardiac conditions. Here sterilization is usually added.
8. Instead of high forceps on the floating head in non-infected cases.
9. Once a Cæsarean, always a Cæsarean.
10. Gunshot wound through gravid uterus (suggested by Zincke).
11. Moribund or dead mother with living child.
12. Tonic contraction of uterus and dry labor (suggested by Davis).
13. Prolapse of cord with undilated cervix (suggested by Davis).

From this limited experience of my own, from assisting others, watching the results of my colleagues, and a careful study of the literature, I am convinced that obstetrical Cæsarean section is a simple, sane and safe procedure in uninfected cases, and that in proper surroundings with proper assistance the indications for this procedure can be greatly broadened to the advantage of mother and child. It gives the mother an almost painless labor, a speedy convalescence, and perfect health when all is over, with freedom from the troubles and complications of cystocele, rectocele, lacerated cervix, and prolapse, not to mention what we see frequently enough after difficult instrumental deliveries, fistula from vagina into rectum or bladder, or incontinence of feces or urine. For the child it practically does away with the possibility of fractures, palsies, cerebral injuries, and disfiguring marks of forceps. It is time that the general practitioner, the family doctor, who has been called the "obstetrician of America," learned that there is a safe method of delivery in complicated but uninfected cases, that is free from the mutilating effects of forceps, version, and the like, and it is time that this same truth was brought home to the laity.

2 West Eighty-sixth Street.

Wassermann Reaction in Scarlet Fever.—G. F. and G. R. Dick (*Journal of Infectious Diseases*, August, 1916), as a result of their investigations, came to the conclusion that positive Wassermann reactions in scarlet fever, obtained with acetone-insoluble portions of alcoholic heart extract, are strongly suggestive of syphilis.

Our Readers' Monthly Prize Discussions

Twenty-Five Dollars Is Awarded for the Most Satisfactory Paper

All persons, whether subscribers or not, are invited to compete for the prize of $25 offered for the reply deemed best by the editors to the following questions:

CLXXIV.—How do you treat ivy poisoning? (Closed.)

CLXXV.—How do you treat furunculosis? (Answers due not later than October 16th.)

CLXXVI.—How do you treat Colles's fracture of the radius? (Answers due not later than November 15th.)

The award will be based solely on the value of the information contained in the answer. No importance will be attached to literary style. Answers should preferably contain not more than six hundred words, and should be written on one side of the paper only. All papers submitted become the property of the JOURNAL, and should bear the full name and address of the author for publication. The prize will not be awarded to the same person more than once within a year.

The prize of $25 for the best answer to Question CLXXIII was awarded to Dr. A. W. Nelson, of Cincinnati, Ohio, whose paper appeared on page 700.

PRIZE QUESTION CLXXIII.
THE TECHNIC OF CIRCUMCISION.

(*Continued from page 703.*)

Dr. Willis H. Hall, of Carina, Cal., remarks:

No matter what condition calls for this operation, the method is practically the same; the object is to dispose of most of the prepuce so that the end result is good as regards appearance and function. To attain these results I have found the following procedure satisfactory:

As to the anesthetic, in children and in young persons, a general anesthetic is to be preferred, to guard against the needless struggles which ensue from fright when a local anesthetic is used, as children are easily frightened and will not remain quiet even if there is no pain. In those who are older a local anesthetic may be used to advantage. My choice is novocaine one per cent. sterile solution to which is added just before use adrenaline chloride twenty drops to the dram, the solution being sparingly instilled to prevent excessive deformity of the parts. Quinine and urea hydrochloride, cocaine, beta eucaine have all been used with satisfaction.

Previous to injection a constricting band should be placed around the penis near the root. An ordinary elastic rubber band is sufficient, and should not be too tight, only enough to retard the venous circulation. The parts should then be thoroughly but gently washed with warm water and tincture of green soap, followed by alcohol and a very thin coating of tincture of iodine. The syringe should be sterile and the needle sharp. The patient should feel only the first puncture and the line of the injections should follow the line of intended incisions. Test with the needle point to ascertain when anesthesia is sufficient to begin the incisions. If a general anesthetic is used, the washing is postponed until the operator is ready to go to work. In any case the operative field should be protected by sterile towels.

In case of a paraphimosis, it should be reduced, and the operation conducted as usual. In some cases there is a great swelling which obliterates the usual landmarks. The penis becomes twisted on its own axis, from tension on the frenum. In this case there will be a sulcus at the site of the frenum and the incision is started on the side away from the sulcus.

In making the dorsal incision, it is well to insert a grooved director beneath the tissues and then divide with scissors, one blade sliding in the groove director to avoid damage to the glans. The incision should be made about two thirds of the distance from the urethra to the corona, as the skin will retract on account of its elasticity. The dorsal incision having been made, it is well to retract all tissues over the glans, breaking up adhesions. If phimosis or adhesions prevented the washing of these parts previously, it is well to wash them at this time. The next step is to sever the redundant prepuce by making an incision in the line of the corona, from the dorsal incision to the frenum, first on one side and then on the other, afterward trimming the deep layer of the prepuce to correspond with the retracted outer layer, so that the deep layer is left about an inch long. The next step is the suture of the two layers of the prepuce with fine catgut or silk; interrupted sutures giving better satisfaction than the continuous suture. By coapting the two layers with properly placed sutures, healing takes place more rapidly than if there is a gap left to become infected and produce irritation. The constricting band may be removed and the parts well washed in flowing hot water or normal saline. This cleanses the parts and helps to limit the swelling caused by the operation as well as to control hemorrhage.

The dressing most satisfactory to me is gauze saturated with pure olive oil, sterile and applied freely. The gauze dressing is applied in two parts, the first consisting of a square of gauze with a small hole in the centre, which is enlarged with the finger to a size which will pass partly over the glans but not over the corona. The second piece of gauze is like the first, except that the centre opening is larger and should slide over the first piece like a collar; the fullness is turned toward the distal end of the penis, so that when complete the fullness of the two pieces of the dressing lies in two different directions. This second piece of gauze thus covers the glans and the meatus, and may be turned back when the patient urinates, the first piece of gauze remaining undisturbed.

With care this dressing may be kept clean till time to change it, which should not be for five days, when union should have occurred. With proper care the wound should be clean. In most cases a

second similar dressing should be all that is required.

Where there is subpreputial chancre or chancroids or a badly infected urethra, not many primary unions occur, there being usually one spot which has become infected, and the treatment should be that of the source of the infection. If it is infected from a chancroid, it is best to consider the infection a chancroid and treat it as such.

Dr. J. Otis Carrington, of Malden, Mass., says:

We must remember that the skin of the penis is loose and capable of enormous distention owing to extravasation of blood from uncontrolled bleeding points which may lead to hematoma. Great care must be exercised to estimate accurately the amount of prepuce to be removed so that the glans penis is just covered when the organ is flaccid and contracted.

Local infiltration with novocaine one per cent. is necessary, except in infants and young children, where general anesthesia is employed. Local infiltration should follow the lines of incision elected and should be made both into the skin and beneath the mucous layer of the prepuce. Novocaine four per cent. must be held in the preputial cavity or applied within the cavity on a pledget of cotton for five minutes. The entire preputial cavity and prepuce should be thoroughly washed with soap and water and some nonirritating antiseptic fluid.

When the preputial orifice is narrow, but not abnormally long or redundant, a longitudinal incision along the dorsum of the penis suffices. Pass a broad, flat grooved director between the prepuce and glans, one blade of probe pointed scissors being passed along the groove. The incision should extend a short distance beyond the corona. If the lining membrane of the prepuce is redundant—it usually is—clip the excess away, leaving a cuff of one quarter inch with which to unite the two layers of prepuce, using a continuous suture of fine catgut. Dress with sterile gauze.

When the prepuce is abnormally long, the redundant portion must be removed. All adhesions between the lining membrane and glans should be separated by retracting the prepuce as far back as the corona. Now, draw the prepuce forward over the glans and gauge very carefully the amount of redundant tissue to be removed. Then grasp it in front of the glans with a pair of clamp forceps, applied obliquely from above downward and forward. The portion in front is cut away with a bistoury, leaving a cuff of mucous membrane one quarter of an inch broad. Remove enough skin so that the glans may be well exposed, but be careful not to expose the sensitive papillæ of the corona. On removing the forceps, slit the lining membrane of the prepuce that still covers the glans up along the dorsum. The excess is cut away with scissors, making allowance for the cuff. Arrest bleeding by fine catgut ligatures. Pass four sutures of nonabsorbable material, silk or silkworm gut, uniting the cut skin margin to the cuff; one in the median line of the dorsum, one in the median line of the inferior surface at the frenum, and one on each side half way between these points. A few additional sutures will approximate all the margins.

Hemorrhage should be carefully controlled at bleeding points by hemostatic forceps and ligatures of No. 0 catgut. Apply a band of folded sterile gauze over the line of sutures and retain them by strips of zinc oxide adhesive plaster applied over the gauze. Do not apply the dressing too snugly. The penis should be held upright in a ring or dressing attached to a waistband.

Erections are painful, very annoying at night, and may tear the suture line and cause considerable hemorrhage. The sutures should remain in place from five to seven days. Rest by recumbency for two or three days hastens healing and diminishes painful erections. Sodium bromide grains xl, in a glass of water on retiring is valuable to control nocturnal erections. A clean, wholesome environment and nonstimulating food and drink should be given.

Do not apply permanent dressings. To do so is to invite decomposition, irritation, and possibly infection through urine retained in the meshes. Furthermore, a permanent dressing becomes hardened, heavy, bloody, and foul from the oozing of blood. Change the dressings as frequently as necessary to maintain cleanliness, insisting each time upon the use of sterile dressings.

Dr. A. Julius Gordon, of Newark, N. J., announces:

The operation of circumcision may be best discussed under the following heads:

1. Anesthesia.
2. Preparation.
3. Procedure.
4. Aftertreatment.

Anesthesia.—In very young infants I have obtained the best results by employing general anesthesia by ether or chloroform. In adults, except those of a decided neurotic taint, local anesthesia has yielded good results. I use either a solution of cocaine (0.25 per cent.) or a one per cent. novocaine solution. I make my first injection about an inch behind the corona and at varying intervals anesthetize the subcutaneous tissues just up to the corona. After waiting from five to seven minutes I am ready to perform the circumcision; no further injection is then required, except in some cases the further injection of a drop or two into the frenum.

Preparation.—The inguinal regions, scrotum and penis are thoroughly scrubbed for five minutes with green soap and water. The soap is washed off with sterile water, and the areas described are then washed off with a weak solution of bichloride of mercury. A sterile urethral catheter is then tied around the base of the penis, to act as a tourniquet to prevent bleeding. The penis is draped by placing one sterile towel on each surface of the base and holding these in position with towel clasps.

Procedure.—The prepuce is grasped by two small hemostats, one on the dorsal surface and the other on the ventral surface, close to their margins. The prepuce is then put on the stretch. A large curved artery clamp is then placed transversely across the prepuce close to the corona. Then, with a sharp scalpel, the foreskin above this large clamp is cut away, keeping the blade of the knife close to the clamp. The clamp is then removed, and the re-

dundant mucous membrane is seized with two small clamps in exactly the same way as the skin was. A dorsal slit is then made with a sharp pair of scissors, and the redundant mucous membrane is removed by cutting around the circumference of the penis, up to within an inch of the corona. Great care should be taken not to cut the mucous membrane too short, and it is best left "untrimmed" once it is cut.

The rubber catheter is now removed from the base of the penis and any bleeding is stopped, with either a hemostat or a catgut suture. The mucous membrane and skin are now grasped with a pair of forceps, and catgut sutures (No. oo or o catgut) are passed through these tissues. The sutures are put in about a quarter of an inch apart. The sutures are tied very loosely, not too tight because of the danger of edema and sloughing. The ends of the sutures are left long for the iodoform dressing. A strip of iodoform gauze, about one half to one inch in width, and of sufficient length to be wrapped around the penis, is then applied as a dressing to the operative surface. The iodoform is greased with sterile petrolatum, and is held in place by tying the long ends of the sutures. A sterile dressing is then applied and the operation is finished.

Aftertreatment. The patient, if at home or in the hospital, should be in bed for twenty-four hours. I usually give thirty grains of the triple bromides as a standard dose in order to prevent painful priapism, which frequently occurs. The dressing is changed the second day after operation and is then renewed every day or other day as the case requires. In seven to ten days the iodoform gauze usually drops off owing to the absorption of the catgut, and the wound is completely healed, except for a few raw spots, which clear up quickly when dressed with boric acid ointment.

Dr. Walter W. Sale, of Covington, Tenn., describes how:

The day before the operation is to be performed, I have patient shave all hair from mons pubis and scrotum, give him a few bichloride of mercury tablets and tell him how to make a one in 5,000 solution. I have him wash his penis, testicles, and lower abdomen two or three times the day before operation, and again about an hour before the operation. Immediately before operation I cleanse the above mentioned parts with the same solution, dry, and sponge with ninety-five per cent. alcohol. I then paint entire skin of penis with tincture of iodine; cut a small hole in a sterile towel just large enough to allow the penis to pass through, making a tight fit. The towel covers all except the field of operation.

For an anesthetic I use a two per cent. solution of cocaine as it takes a very small amount. First I inject about two drops under the skin of the dorsum of the penis midway between the distal and proximal ends. This does away with practically all pain that might be caused afterward.

I now begin at the median line on top and infiltrate the skin around the penis along the line that the incision is to be made. This requires only a few drops, maybe twelve or fifteen. This being finished, I massage the penis for a few moments by rolling it between my fingers and thumb. This gentle massage causes an even distribution of the cocaine solution and therefore thorough anesthesia.

I begin the operation by making a skin clip in the middle of dorsum in line with, and about one sixteenth of an inch behind the corona, taking care not to cut the mucous membrane, as the point of my operation is to remove the skin and mucous membrane separately.

I now slip the blade of a pair of pointed scissors into the skin opening and complete the incision on one side, following the curve of the corona to the frenum. A similar procedure is carried out on the opposite side, making the two incisions meet.

The foreskin now draws and shrivels, making the removal of the mucous membrane easy.

For the removal of the mucous membrane I first attach five hemostats at the edge of the foreskin, two at the top, one at each side, and one in the middle of the frenum, an equal distance apart, except the two at the top, which are very close together. I then make a dorsal slit between the two hemostats at the top to one fourth of an inch of the insertion of the mucous membrane behind the corona. I then pick up the two top hemostats on one side and have an assistant hold one at the middle of the frenum. I put just enough tension on these three hemostats to enable me to make a straight incision from dorsum to frenum. When I reach the frenum I direct my incision outward, and remove the membrane without cutting the artery of the frenum. This is almost a certain guarantee against hemorrhage of any consequence. The opposite side is removed in the same manner. I now hold the penis at site of incision firmly between my fingers in order to stop bleeding, if any takes place. I then paint the entire raw surface with pure tincture of iodine, and suture. I consider the suturing and suturing material very important.

The most important part of every operation is the result, and for a perfect result in a circumcision operation the skin and mucous membrane must be held in perfect apposition. Add a stitch so long as there remains a gap between skin and mucous membrane, regardless of number.

For suturing I use No. o plain catgut. I never have to remove a stitch. I remove the dressing on the third or fourth day. By this time the skin and mucous membrane are united perfectly and all the sutures hold without the slightest tension.

Dr. A. B. Pemsler, of New York, among others gives these details:

If adhesions are present the foreskin is pulled back and they are broken up. This step is very important in order that a good result be obtained. After this is done the parts are thoroughly cleansed with tincture of green soap, followed by an antiseptic dressing. In an adult it is even advisable to shave the pubic hair in order to obtain as clean a field as possible.

In suturing, I usually use silk. I leave the ends long. My dressing consists of a sterile gauze strip, which I place around the wound and keep in place by tying with the ends of the sutures left for this purpose. This dressing may be used only with

adults who can be instructed to avoid wetting the dressing In children I apply the ordinary sutures, a dry sterile dressing, and instruct the nurse to wash the part with a solution of boric acid after the child urinates. The sutures are removed in about a week.

Abstracts and Reviews.

THE MANAGEMENT OF POLIOMYELITIS.*

With a View to Minimizing the Subsequent Disability,

By Robert W. Lovett, M. D.,
Boston.

Dr. Robert W. Lovett said that in regard to poliomyelitis he had no startling facts to bring forward, no new discovery, no revolutionary therapeutic measures; but it seemed to him that the data already accumulated were sufficient to warrant renewed study to see if encouragement could not be found for greater hopefulness in the outlook and for greater efficiency in the treatment. There were in New York city today several thousand children paralyzed during the last few months, and in the rest of the country several thousand others, and the problem of treating these children in the best possible way was not only a surgical and humanitarian one of great present interest and importance, but an economic question of no mean dimensions. The best brains in the country had been organized for the study of the epidemiology and pathology of this disease and the task was being taken seriously.

Although the work of such men was the more important, because prevention was better than cure, it was none the less imperative for clinicians to take their own problems just as seriously and to inquire into the efficacy of the present methods and the possibility of improving them. It was their business to see that the wreckage left behind these epidemics was efficiently and economically cared for.

Orthopedic surgeons largely prescribed braces, with perhaps massage or electricity, or muscle training as probably of use, and had been much interested in the operative question. The neurologists had been less enthusiastic about braces, but had on the whole favored electricity, about the value of which there was no controversy. The general practitioner had often ordered braces and had felt that electricity and massage were of use; but on the whole all had regarded the affection as an undesirable one to treat and a tiresome thing to have anything to do with, except in its operative aspect.

In surgery the treatment of poliomyelitis was one of the most gratifying and satisfactory problems for the reason that nowhere did the close analysis of each case and the application to it of commonly accepted anatomical and physiological principles yield more satisfactory results; the problem in every case, after the acute attack, was one in functional anatomy, exact, clean cut, and clear; the final functional results were in most cases largely influenced by the precision, efficiency, and persistence of the treatment, especially in the early stages; and certain phenomena of the disease, clinical and pathological, warranted holding out to these patients a much larger degree of hopefulness than had previously been possible. This statement could be substantiated in figures. Operations were performed, first, to improve existing function; these operations were tendon transplantation and nerve transplantation. The second class were done to secure better stability in badly paralyzed joints; to this class belonged artificial ankylosis, the use of silk ligaments, tendon fixation, and the removal of the astragalus with backward displacement of the foot.

It was unwise to operate in poliomyelitis, except to correct deformity, until after the lapse of two years; many surgeons believed this period better deferred for three or four years, or even to later childhood; but if, for instance, the change of tendons to rebalance the foot was deferred too long, bony deformity might be acquired and deterioration of stretched muscles might occur. A quantitative examination, such as the Martin-Cannon muscle test afforded, might in the individual case give much information as to the proper time for interference, so that in some cases two years would be long enough to wait, while in others it might be wise to defer operation in an attempt to develop certain muscles in younger children. The more destructive operations, necessitating the removal of bone, might better be deferred; extensive operation in young children was not desirable, even in the case of tendon transference. It was also manifestly sound surgery to see that as many operations as possible were avoided by careful treatment.

Anterior poliomyelitis was to be regarded as an infectious disease accompanied, in a certain proportion of cases, by paralysis. Paralysis was accidental and incidental; the infection was the central fact. In this paper, however, the paralytic form was under consideration. The clinical expression of the processes effected by the invasion into the system of the infectious agent was a widely distributed and erratic motor impairment, accompanied in most cases at the outset by great tenderness over the affected area. There was a mechanical anemia of the motor cells in the affected areas of the cord; these cells might recover, or go on to necrosis. The edema of the affected part of the cord interfered with motor function in the edematous area. Hemorrhages, if in the neighborhood of motor cells, might abolish their function. If the patient lived, the perivascular infiltration and edema subsided gradually or quickly and the hemorrhagic products were absorbed, leaving behind the areas too much damaged to recover, which were converted into focal scleroses. First there was an acute hemorrhagic myelitis; second, a convalescent myelitis with returning power, and, third, a cord, in the motor area of which were scleroses, all stages accompanied by more or less motor impairment. No one treatment could be advocated for all these stages, and there must be a clear distinction between the different phases of the process in considering therapeutics.

The stage of onset covered the period from the beginning of the illness until the disappearance of tenderness, which was evidence of an active process

*Abstract of paper read at Academy of Medicine meeting, Oct. 5, 1916.

still existent in the cord. In exceptional cases, where tenderness was absent, this stage might be counted as lasting from four to six weeks. The stage of convalescence began with the disappearance of tenderness and lasted about two years. The chronic stage apparently began on the average of about two years from the onset and continued through life.

The method of Professor Martin and Professor Cannon, of Harvard University, was a quantitative standard of examination; it consisted in ascertaining the strength of twenty-two different muscle groups on each side of the body in their resistance to the pull of a spring balance. Through this method an accurate study of the phenomena presented by the affected muscles was possible and led to the conclusions set forth in this paper.

Partial paralysis was more common than total. Total paralysis, when it existed, did so below the knee. Therefore they were not dealing with a hopeless loss of power, except in a small percentage of the muscles, but with a weakening which was of various grades. It should therefore be the aim to conserve, stimulate, and improve such weakened muscles with a view to bringing them as near to normal as possible.

A factor of much importance in the matter of securing muscular improvement lay in the existence of possible spontaneous improvement which started as soon as the tenderness disappeared, and continued for a long time. It should always also be borne in mind that fatigue and overexercise, therapeutic and otherwise, were dangerous.

Treatment in the acute stage should lie in rest and in the absence of irritation and meddlesome therapeutics. Deformities might occur in two or three weeks after onset and should be prevented by the support of plaster of Paris splints, or some similar simple appliance. A warm saline bath immersion was agreeable and apparently beneficial toward the end of this stage. There was reason to hope that the intraspinous administration of the blood serum of recovered patients, as early as possible in the onset of the disease, was a therapeutic measure of value in diminishing mortality and limiting the paralysis.

During the convalescent phase they faced squarely the question of muscular care and development. The destructive process had ceased, the harm had been done, and the development of the possibilities of what remained was the problem. In this stage the amount of ultimate function was determined. Spontaneous improvement was more marked in the first six months than in the second six, and more marked in the second six than in the last six months of the two year period allotted to this stage. The gastrocnemius muscles gained in strength when walking was restricted and if the muscle was judiciously exercised. This pointed to a general rule governing the behavior of other muscles.

Soon after the acute stage was over, it was better to get the patient on his feet—that is, within two or three months of the onset of the attack. Prolonged recumbency was not favorable to circulation, and the nervous system of children was undesirably affected by prolonged confinement. It was important to remember, too, that when the patient was put on his feet, there was an instinctive effort to balance and hold himself upright, which exercised muscles otherwise not to be reached; but fatigue should be guarded against.

Braces, corsets, and other forms of apparatus were compensatory rather than therapeutic. They enabled the patient to get about while massage, muscle training, the avoidance of fatigue, and perhaps electricity hastened the repair of the local process. Braces prevented muscular stretching and the loosening of joints, and controlled deformity.

The three chief measures for improving the condition of the neuromuscular mechanism were massage, electricity, and muscle training. The effect of massage was largely local and harm could be done as well as good.

Faradic electricity was disagreeable, but probably mildly effective in exercising muscles which would not contract voluntarily. Galvanic electricity and the newer forms, such as high frequency, sinusoidal, static, Morton wave currents, etc., were supposed to work, in a way less definitely understood, in increasing muscular power and improving nerve conductivity; but until the case for electricity was definitely proved, it was better that it should not constitute the whole treatment and it should not be carelessly applied by laymen.

Muscle training more closely met the requirements indicated by the pathological conditions in this stage. It was an attempt to reconnect a cerebral motor impulse with a peripheral muscular contraction when the normal connection had been lost or impaired by injury to the motor centres in the cord occurring in the acute stage, so that cerebral motor impulses were checked or diminished at these impaired centres, and the muscular contraction occurred feebly if at all. This method aimed to force the efferent impulse to create a new path along the disordered nerve centre in the cord and also to secure contraction of the desired muscle. These attempts rested on a sound anatomical and physiological basis; unless the destruction in the cord had been excessive, there was a possibility that some new path, or combination of paths, could be established to carry a motor impulse in some degree around the damaged area. In muscles not totally paralyzed, there was every prospect to expect continuous muscular improvement from repeated attempts to drive a motor impulse from brain to muscle and a permanent improvement in conductivity. Muscles partially paralyzed in poliomyelitis required an extremely small dose of exercise.

Deformities as they occurred in this stage should be removed.

The impression the speaker wished to convey was that the use of braces was conservative and preventive, rather than therapeutic; paralytic poliomyelitis was more often a weakening of the affected muscles than a total paralysis, and conservation and improvement of such muscles should be the main treatment, and, to be effective, such treatment must be based on a thorough and accurate muscular diagnosis and must be carried out with optimism, persistence, and accuracy. Under these conditions the treatment was effective in influencing ultimate function.

Dietetics, Alimentation, and Metabolism

Food and Food Preparation, in Health and Disease

FOOD AND EFFICIENCY.

By Martha Tracy, M. D.,
Philadelphia,
Professor of Physiological Chemistry, Woman's Medical College of Pennsylvania.

INTRODUCTION.

Efficiency is a watchword of the present generation. In this day a man is keen to learn how his business may be conducted more efficiently, how he may accomplish more, make more money, get more work out of his operatives, with the least possible waste of effort or loss of time or energy.

The measures taken to secure greater efficiency in business do not always consider the well being of the individual worker, although the idea has dawned, and now here, now there, is gradually advancing, that the health of the man or the woman at the machine or at the desk is of far greater significance, from the point of view of accomplishment alone, than the factory owner or managing clerk was formerly accustomed to think. Those in control begin at last to see that they will get more productive effort out of men or women who are well and in good spirits and working among healthful surroundings than out of workers who are below par physically, and are dulled by the stifling atmosphere of unhygienic workrooms.

In her comprehensive brief, *Fatigue and Efficiency*, published by the Consumers League of New York City, Josephine Goldmark has shown that work fails to be productive if carried beyond a certain point of fatigue in the worker. Professor Münsterberg, of Harvard University, calls attention in the *Psychology of Efficiency* to the desirability of the task's being appropriate to the mental calibre of the individual, if efficiency is to be expected.

A phase of this efficiency problem which has not been fully appreciated by the public is that suggested by the title of these papers; the relation of food to efficiency. Perhaps the delay in appreciating and attacking this phase of the problem, or the lack of momentum in the attack thus far, is due to two causes. One is the fact that here is a matter—the proposition of the food any individual eats—which is distinctly personal. What I eat is my business and what you eat is your business, and no one has a legal right to say that you and I shall change our habits in this regard.

In other matters of health, influenced no doubt by their bearing on business efficiency, public opinion has concluded that it has a right to express itself legally, and so laws have come to be which limit hours of labor to such as shall be short of excessive fatigue; and the ventilation and hygienic conditions of workrooms become matters of statute. In regard to food, however, beyond taking measures to prevent the selling of poisons or adulterated food substances, the law does not go. The freedom of the individual to eat or to starve is sacredly preserved.

The second cause for the ignorance and indifference to this subject is to be acknowledged with regret, that those of us who have learned by scientific study the very close relation existing between the amount and kind of food eaten and the efficiency of the human machine have not made clear to the public, in practical and comprehensible terms, what we have learned.

The average practising physician has not, up to the present time, been adequately trained in the subjects of nutrition and practical dietetics, and is not able to give clear and explicit information and directions to patients in regard to the purposes and caloric value and digestibility of individual food substances. I recall an instance reported in my own office of an estimable family physician, who when implored by a patient to tell her definitely what she might eat to meet or to avoid the exigencies of her condition, would reply only, "A little mutton broth is good."

It is exceedingly desirable that a wider scientific knowledge of these subjects among practising physicians should be interpreted by them to their patients in practical terms applicable to everyday domestic use.

Though both scientific and popular literature now abounds with expositions of the subject, the greater part of the material presented is either so popular as to be inaccurate, or so elaborate and involving the use of tables of food values which are unwieldy for practical use by the physician, and quite incomprehensible to the patient and the public at large. The subject has not yet been presented in a manner which though scientifically accurate is sufficiently simplified to interest and captivate the public imagination.

In this age of increasingly wonderful machinery, the human machine, far more mysterious and wonderful than any engine built by man, should furnish a subject of fascinating interest to every man, woman, and child, and this interest should be readily translatable into management of that machine in such a way as to produce a maximum of efficient work.

Through the writings and addresses of such men as Professor Lusk, of Cornell University, Doctor Bolduan, of the New York board of health and of the New York Medical Journal, and others, a beginning of this campaign of education has, however, been made. Thus we may hope that the future will see both preventive medicine and curative medicine helpfully advanced through popular applied dietetics.

The intelligent and effective practice of dietetics requires an appreciation of the principles of nutrition and a fundamental knowledge of the chemistry of the essential foodstuffs. It is hardly possible to introduce this subject without brief reference to the great French chemist, Lavoisier, who in the years 1776-77 discovered and demonstrated the importance of the gas, oxygen, in

the life processes of animals. By this discovery he opened up the modern era of the science of nutrition and laid the foundation for the far reaching experiments which, during the last century and a quarter, have established our knowledge of the body processes on an accurate scientific basis.

Lavoisier himself was guillotined during the French Revolution, in 1794, while begging for two weeks more of life in which to complete experiments already begun, and of which an abstract report only is available. But a long list of chemists and physiologists have carried on the work, and through painstaking and laborious experiments, made possible by the gradual development of new and constantly more accurate and delicate methods and apparatus, facts have been accumulated which today enable us to lay down with confidence certain well established principles of nutrition.

The earliest observers in this field noted that though a normal man may consume a large amount of food, he does not vary to an appreciable extent from day to day in size and weight, and since the material lost in the excretions from the kidney and bowels did not balance the weight of food eaten, there must be other material loss, presumably of gases, which were in these early days included under the term "insensible perspiration."

Lavoisier showed that about one fifth of the atmosphere surrounding the earth consisted of the gas, discovered by Priestley, which he called oxygen, and that when wood or other fuel substances burn in the air, what actually takes place is a chemical change, a combining of oxygen with the substance of the wood or coal, this material being consumed more or less completely, and invisible gaseous products being formed. During this chemical process of oxidation, the potential energy which was latent in the materials of the wood or coal is transformed into and set free as heat and light.

This investigator observed that as a candle would not continue to burn in a jar from which a fresh supply of air was excluded, so an animal, a mouse, could not continue to live in a similar closed space. He was the first to become convinced that the life of animals is dependent upon absorption or inspiration of oxygen, and that animal heat, like the heat produced by a burning candle, is derived from oxidation of the material of the body, and that the same gases are produced by this oxidation or combustion in one case as in the other. He wrote: "Respiration is only a slow combustion of carbon and hydrogen, similar in all respects to that which takes place in a lamp or lighted candle; and from this point of view animals which respire are truly combustible bodies which burn and consume themselves."

The animal body then could be regarded as a machine or engine dependent for its driving force upon the oxidation or burning of fuel which is supplied in the form of food, and which disappears as such within the body furnace, but by its combustion or oxidation, yields energy in the forms of heat and mechanical work. It became at once an interesting problem to measure and compare the fuel value of materials burned in an ordinary stove, with that of the foodstuffs which are the fuel of the animal furnace.

As is well known, it has been found convenient to measure the fuel values of different materials in heat units which are called calories, each large calorie being the amount of heat necessary to raise the temperature of one kgm. (2.2 pounds, about one quart) of water 1° C. (1.8° F.).

This fuel, or heat producing value of any combustible substance has been determined by oxidizing a definite weight of that substance in the bomb calorimeter. When one gram of coal—almost pure carbon—is completely burned in such a calorimeter it produces 8.08 calories—i. e., sufficient heat to raise the temperature of one kgm. of water 8.08° C. By union of oxygen with the carbon during the combustion, the gas carbon dioxide is produced.

The substance of foods which are the fuel supply of the animal, are conveniently grouped in the chemical classes, carbohydrates, fats, and proteins, to which we must add the nitrogenous compounds of rather vague nature now known as vitamines, and the inorganic substances—water and salts.

Carbohydrates include the sugars and starches. They contain the elements carbon, hydrogen, and oxygen, and when they are oxidized or burned, more oxygen combines with these elements, heat is liberated, and the gases, carbon dioxide and water vapor, are produced.

Fats include such compounds as butter, lard, suet, olive oil, etc. They also are composed of carbon, hydrogen, and oxygen, but they contain a good deal less oxygen in proportion to the carbon and hydrogen, and so require more additional oxygen to burn them, and they liberate more heat weight for weight, when burned, than do carbohydrates. They also yield on combustion, carbon dioxide and water.

Proteins, the so called albuminous substances, are found chiefly in eggs, milk, and cheese, meat and meat products, fish, poultry, and to a less extent in vegetables, especially cereals, peas, beans, and nuts. These compounds contain also carbon, hydrogen, and oxygen, and in addition *nitrogen,* and often phosphorus, sulphur, and iron. When oxidized they liberate heat and yield the gases, carbon dioxide and water, and also certain other compounds derived by oxidation of the nitrogen, phosphorus, and sulphur. Proteins, therefore, have a composition and a value to the body in addition to and quite different from that of carbohydrates and fats. We shall discuss them later.

When these food substances, the fuels of the body, are burned in the bomb calorimeter, it is found that they have the following heat producing or caloric values:

1 gram of carbohydrates	=	4.1	calories
1 gram of fat	=	9.45	calories
1 gram of protein	=	5.65	calories
(about 30 grams = 1 oz.) or			
1 oz. carbohydrate	=	123	calories
1 oz. fat	=	283.5	calories
1 oz. protein	=	169.5	calories

and each gram of carbohydrate, or of fat, or of protein, burned, produces a definite amount of carbon dioxide and of water.

(*To be continued.*)

Lysine.—Data collected by Osborne and Mendel show that lysine, as found in casein, lactalbumin, and egg vitellin, is indispensable for the functions of growth.

DIET AND GROWTH IN INFANTILE SCURVY.*

By Alfred F. Hess, M. D.,
New York.

With Part of the Subsequent Discussion,

Doctor Hess had noted a gradual falling off in growth at about the seventh or eighth month in babies that had been fed on pasteurized milk, and had made an experimental study to find whether this might not be due to a lack of the elements essential for growth in this diet. Many of these infants did not show typical symptoms of scurvy, the disease being in an obscure or subacute form, which he considered the most common and the least frequently recognized. Tachycardia was, however, an early and typical symptom.

He found that growth in both length and weight was greatly affected in infants fed exclusively upon pasteurized milk, both finally ceasing. When orange juice, orange peel juice, or potato water was added to the diet, there was often a supergrowth, which continued until the normal weight and length for the infant's age was reached, when the growth became normal. After discontinuance of this antiscorbutic food, although the infants sometimes continued to gain for a month or two, there was a gradual flattening of the curve of growth. As soon as orange juice was again given, however, a sharp gain was manifested, showing that the babies were receiving some essential constituent of the diet that had been lacking.

Doctor Hess also found that putting these children on unpasteurized milk had the same effect as giving fruit juice with the pasteurized milk. He then investigated the effect of boiling on both milk and antiscorbutic foods, and found that orange juice and orange peel juice did not lose their antiscorbutic elements by being boiled, although milk did. He concluded that while pasteurized milk should be recommended, on account of the security that it afforded against infection, it should be considered as an incomplete food, lacking the elements essential to proper nutrition and growth. He thought it probable that this was why so many infants failed to gain at about the seventh or eighth month of life, and began to grow better as soon as fruits and vegetables were added to their dietary. He thought that during the early months of life the infant was protected by the antiscorbutic elements inherited from its mother, and recommended orange juice at the age of one month, so as to prevent the development of the scorbutic state.

The doctor admitted that there might exist a number of causes for lack of growth; insufficient food, lack of proper elements in the food, etc. He thought, however, that other elements than lack of growth were concerned in the production of infantile scurvy, and did not consider stunting and scurvy as the same; as the diet might possess growth-promoting qualities, and yet be unable to prevent the development of scurvy or afford a means of curing it.

Doctor Holt thought that Doctor Hess had proved the point that had been under discussion from time to time, whether pasteurized milk could be held responsible for scurvy. It had been his observation for several years that such was the case, and a number of instances had come under his observation during the last year to confirm his earlier position. While they all admitted the great advance which had been brought about by the introduction of pasteurized milk in securing safety in cases in which doubt existed as to the way in which the milk was produced and handled, the disadvantages of pasteurization had sometimes been denied and sometimes ignored—and, on the part of the dealers supplying pasteurized milk, disputed. Unless they who were interested in the production of good milk and certified milk made strong their disapproval of the general pasteurization of all milk, it would not be many years before they should be face to face with the fact that it was impossible to secure any but pasteurized milk. In one city in New England, the health department was about to issue an order that no milk but pasteurized should be sold in that city, regardless of the conditions of production or certification. In a number of instances, certification had been done by irresponsible persons, and was later shown to have been a fake. Physicians had been in part responsible for this; and even they, perhaps, had been negligent. He believed, however, that in the matter of pasteurized milk, they must admit that scurvy, every now and then, followed its use—and many other conditions. In some persons there was a predisposition to scurvy which they could not ignore; and while comparatively few children on pasteurized milk got scurvy, some did. When they saw groups of dealers banding themselves together to get legislation through State legislatures or health departments forbidding the sale of any but pasteurized milk, they should show that there were dangers in the use of the latter. They saw bad results from its use less frequently among the babies of poorer people, because this class gave food other than milk to their infants much earlier than had been customary among the better class of people. It had been his observation, that, while nearly all the cases of scurvy used to come from the use of proprietary foods, they now came from employing heated milk, either pasteurized or boiled. It was also his observation that the number of cases of scurvy in the community was increasing, and it was a good thing that the matter had been brought before the society; because the number of cases was large. They had four instances in the hospital last year, cases that had been under medical treatment until there was epiphyseal separation at both knees, both shoulders, and both ankles. A vast number of the profession had not had their eyes opened to the dangers lurking in pasteurized milk, and the antiscorbutic treatment to counteract this must be begun early and continued.

The amount of orange juice necessary in these cases was a point of interest. It had been his fortune to see a case develop in the wards in a baby who was taking a good many meals a day and getting a pretty large quantity of carbohydrate food. Nevertheless, scurvy developed.

If Doctor Adams were to select an epitaph to

*Abstract of a paper read at the Twenty-Eighth Annual Meeting of the American Pediatric Society, Washington, D. C., May 8-10, 1916.

be placed on his tombstone, it would be, "He opposed the commercial pasteurization of milk." He had fought this, and was going to continue to fight it as long as he had breath in his body. What Doctor Holt had said, he hoped the society would back up; i. e., that commercial pasteurization was dangerous and detrimental to the health of children. No institution should be advised to use pasteurized milk, just because some sentimental and erratic persons in the community had banded themselves together and decided that all children would be killed with tuberculosis unless their milk was pasteurized. With Doctor Hess and Doctor Holt, he had, within the last ten days, had cases in children that had been fed on the best pasteurized milk delivered in Washington city. That dairy was constantly furnishing him with work on antiscorbutic lines, yet it passed as one of the best dairies in the entire country. He could not understand why Doctor Herrman had asked if the essential antiscorbutic elements were destroyed in the cooking, they were restored by orange juice. To put the children on raw milk and let the orange juice go would settle the question. He hoped that the matter would be thoroughly discussed, and would tell them of an instance in his own experience. He was attending a patient in a certain house, and the father asked the dairyman why he had not sent raw milk, as Doctor Adams had ordered. The dairyman said he had not done so because the milk was not fit to deliver raw. That was the whole secret. It was rotten milk cooked that was being foisted on the community. He hoped that the members would come come out strongly against the commercial pasteurization of milk. He was not opposed to home pasteurization under proper supervision, but was opposed to commercial pasteurization.

Doctor Blackader wished to say one thing to emphasize the importance of this subacute phase of infantile scurvy. This winter he had two cases in which children were brought to his office at the request of the attending physician for obscure symptoms, partly nervous, and associated with defective growth. There was no sign that he could find of infantile scurvy—none of the classical signs; but he felt convinced, from the history, that these children were suffering from defective nourishment in some form. He was remarkably pleased with the rapid disappearance of all the symptoms under the use of orange juice and unpasteurized milk, at the time. It was something new to him, and he intended to bring it before the profession. He thought that it was an original observation, but he must give Doctor Hess credit for first describing this subacute form with defective vitality owing to insufficient nourishment.

Doctor Hess, in summing up, did not feel that the conclusion to be drawn from this paper was that pasteurized milk was not of any advantage. In fact, in his conclusions he prefaced his remarks by saying that it was of advantage. The conclusion to be drawn was rather that pasteurized milk was an incomplete food—that it was inadequate. If this fact was realized, and acted on, it would be a boon to pasteurized milk producers; because there would be fewer cases of scurvy after its use and better results would be obtained with this heated milk. All that was necessary was to give with it, either orange juice or potato water. They could make potato water instead of barley water by using one spoonful of mashed potato to a pint of water. The commercial potato flour had no effect.

Everyone realized that there was a predisposition to scurvy, whether infantile or adult, in certain persons. That was realized a few years ago, when they had so much scurvy aboard ships. It was known now, also, that this was true in connection with beriberi. Some persons got beriberi and some did not, although they had been on the same food and had been to the same places. As regards infantile scurvy, the susceptibility depended partly on the amount of essential substances that the mother had and the food that she took during her pregnancy, as well as upon how long the infants were nursed. Doctor Herrman had asked how it was that boiling the orange juice did not destroy its essential substances, whereas boiling the milk did so. That was well known of various substances. A great deal depended on the medium. Certain substances would stand boiling in a watery solution (for instance, orange juice), where they would not stand boiling in a medium rich in fats and proteids, such as milk. The brain substance made from the hypophysis lost its coagulability after boiling, if undiluted; but if diluted, it would stand boiling. So it had to do with the medium in which the essential substance was.

The symptoms of scurvy were hemorrhages of the periosteum, petechial hemorrhages, hemorrhages of the gums, subperiosteal hemorrhages, hemorrhages into the muscles, enlargement of the heart, tachycardia, and the other various symptoms that he had detailed in two previous papers. The control cases, of which there were as many as those that had pasteurized milk, obtained no orange juice; yet in no instance did any of them have scurvy. When either orange juice or raw milk was given in the cases with scurvy, there was a sharp reaction in weight and in the clearing up of the symptoms. As to what was a vitamine, that was difficult to answer. Funk, who devised the term, thought that he had it isolated; but he found that it was not pure. It was a nitrogenous substance; and this was a good name, because it helped to designate the substance essential in scurvy, beriberi, pellagra, etc. He wished that Doctor Coit would come over to their institution and satisfy himself in regard to the vitality of the children there. They were institution children; but they looked as well as those in their homes. It was a model institution, and had plenty of fresh air. The weight of the children had been taken every day for six months previous to the beginning of the test. It was not as if they came to the institution just as they would to a hospital. Doctor Freeman had asked whether the speaker had tried the effect of orange juice in cases other than those on pasteurized milk. No, not especially. He could look up the charts and see what happened, but he had not made that particular test.

[Initial cleanliness and early uninterrupted refrigeration are the essentials to be insisted upon in any milk supply. Rotten milk is never made harmless by pasteurization.—Editors.]

Food and Feeding in Childhood.—Dr. J. Epstein, of New York, in the *Medical Times* for October, 1916, states that, beginning with the second year, the period of infancy ends, suckling or bottle feeding is over, and the active life of childhood asserts itself. The gastrointestinal tract which during infancy is in an immature state with its physiological functions of digestion not yet fully developed, is now able to digest and absorb a variety of semisolid and solid food. At this age the child usually has a number of teeth already cut through and is able to masticate the food, preparing it for the action of the digestive enzyme. As the child grows older, the articles of food suitable for its digestion multiply, and the simple, uniform, monotonous diet of infancy which consists of milk only, is now changed to a mixed diet.

The diet during childhood may be divided into three periods.

1. Diet during the second year.
2. Diet during the third, fourth and fifth years.
3. Diet during school years.

The diet during the second year is practically a continuation of the diet of the first year and should be given with the same care. Milk still forms the basis of the food, with the addition of protein, carbohydrates, and fats from sources other than milk. Semisolid and later solid food may be gradually added to the diet and the feeding should be at four hour intervals.

The following is a suitable diet list for children during the second year:

1. At 7 o'clock a cup of milk.
2. At 8 o'clock orange juice or the juice from other ripe fruit.

Breakfast at 10 o'clock:

1. A well cooked cereal—barley, oatmeal, wheatena or farina with a pinch of salt and cream.
2. Buttered toast.
3. A soft boiled egg.
4. A cup of milk.

Dinner at 2 o'clock.

1. Soup—chicken, mutton or beef broth, with a little green vegetable and a boiled or mashed potato.
2. Meat—scraped or chopped, to be given during the second half of the second year.
3. Stale bread with butter.
4. Dessert—junket, baked apple or apple sauce.

Supper at 6 o'clock:

1. A well cooked cereal with cream.
2. Zwieback or crackers or stale bread with butter.
3. Cooked fruit.
4. A cup of milk.

At 10 o'clock a cup of milk.

Nothing but water should be given between meals.

After the second year the child is able to digest a larger quantity and a greater variety of food. As the child grows older it is more active and there is a corresponding increase in metabolism. More food is required to replace worn out tissues and to supply heat and energy.

The following diet list will be found suitable for children between the third year and school age:

Breakfast at 8 o'clock:

1. A well cooked cereal with cream.
2. Bread and butter or buttered toast.
3. A soft boiled or poached egg.
4. A cup of milk or cocoa.

Dinner at 12 o'clock:

1. Soup with green vegetables and a mashed or sweet potato.
2. Meat—beef, lamb, or chicken. Fish may be given occasionally.
3. Bread and butter.
4. Dessert—pudding, junket, custard, baked apple, or ice cream occasionally.

Supper at 6 o'clock:

1. Well cooked rice or other cereal with cream.
2. Milk toast or bread and butter.
3. Cooked fruit.
4. A cup of milk.

No food between meals, but water should be given.

The following must not be given to children: Tea, coffee, beer, wine, whiskey, fried food, corn, cabbage, cucumbers, pies, cakes, nuts, raisins, bananas, and candies.

The diet of school children must receive special attention. School days are an extremely active period of life, both physically and mentally; the budding mentality of the young child gradually develops itself and there is an extra demand on the nervous system which increases the metabolic changes of the body and the wear and tear of life. School teachers cannot have much success in teaching hungry children. No pupil can learn the three R's without three meals a day. In a hungry child all the normal processes of life are lowered and the mentality is dulled. The diet of a school child must be sufficient, satisfying, and not monotonous. Milk being easily digested, should be furnished with every meal as a drink. Cream is valuable and should be supplied whenever possible. Eggs and meat are important as they supply a large quantity of protein from which the tissues are built up.

The following is a good general diet list for school children:

Breakfast at 7.30:

1. Fruit.
2. A well cooked cereal with cream.
3. An egg, boiled, poached or in an omelet.
4. Bread and butter, or griddle cakes occasionally.
5. A cup of milk or cocoa.

Dinner at 12.30:

1. Soup with white vegetables and greens.
2. Meat—steak, beef, lamb chops, mutton or chicken.
3. Bread and butter.
4. Dessert—rice pudding, hominy or custard.
5. A cup of milk.

Supper at 6.30:

1. Cold meat or fish.
2. An egg in any style.
3. Bread and butter.
4. Cooked fruit or plain cake.
5. A cup of milk or buttermilk.

Protein, carbohydrates, fat, salts, and water are the principal compounds of which food is composed, and their chemical elements are similar to those of which the body is composed. When food is properly digested and absorbed it replaces tissue waste and supplies heat and energy on which the processes of life depend.

Cooking Meats for Children.—It is important that meats cooked for children should be prepared with care. If meat is plunged momentarily into boiling water or hot fat, the surface albumin is coagulated immediately and the juices are retained with their full flavor. Thereafter a cooking temperature higher than 180° F. (thirty-two degrees below the boiling point of water) is not only needless, but renders the meat less appetizing and less digestible.

SHOULD THERE BE A CHAIR OF MEDICAL ETHICS?

Whatever may have been the disadvantages of the old preceptor system of medical instruction, it had many merits. One of these was the opportunity offered to the student of becoming imbued with the ethics of his profession. This was no unimportant part of medical training. The practice of medicine is above all altruistic; in all of his dealings the doctor is required to put himself last—to serve cheerfully where there is no reward, frequently ingratitude, and sometimes censure; to aid in disseminating information and advice which cut at the very root of his living; and to make the Golden Rule his motto in a world which is run on an entirely different system.

It is inevitable that among a body of men who perform the same service for the same community and yet who must not compete or advertise, there should arise a complicated ethical system. The principles of this the practitioner soon comprehends, but always there arise situations for which there seems to be no exact precedent; one doctor's idea of the right thing to do differs from another's and inevitably some one is offended. If this appears to be a difficulty to the seasoned practitioner, it is much more of a problem to the recent graduate who has had no definite instruction in such matters and may not have been fortunate enough to be thrown in contact with older practitioners who were able and willing to enlighten him. At first, he has only a certain amount of such information acquired in medical school, incidentally as it were.

Across the sea the General Medical Council of Great Britain has passed a resolution providing that in a medical curriculum, under medical jurisprudence or public health, or elsewhere, instruction shall be given as to the public duties of physicians and the recognized rules of medical ethics. This is especially appropriate just now in Great Britain on account of the complications arising from the war, which will be increased when peace is declared and the military surgeons return to their private practice, but it would have been a laudable resolution at any time.

The occupant of a chair of medical ethics obviously could not be dogmatic nor could he deal to any great extent in specific instances. His whole duty would be to lay down the basic principles of ethics, illustrating them with examples. He would also take under his care the instruction of the student in his future duties toward the community as a whole, his responsibility for the accuracy of vital statistics, for the safeguarding of society from contagious diseases, impressing upon him not only the necessity of obeying regulations to avoid trouble with the health officer, but the wider conception of his duty toward society. The future practitioner should be taught, for instance, that it is better to act upon his tentative diagnosis of scarlatina and exercise the necessary precautions to protect the community even if he thereby alienates the family. When we have our young physicians turned out from the schools imbued with such ideals of their profession, then indeed we shall feel that we are on the way toward our highest possibilities as an altruistic body of workers for humanity.

ANALYSIS OF LIVING MATTER BY ITS REACTIONS TO POISONS.

Recent years have seen great advances in our knowledge of the chemical composition of living matter, brought about by the application of the newer methods of chemistry; great as have been these advances, however, they have carried us but a short step farther in our understanding of the structure of living matter and they have been wholly unavailing for the explanation or even discovery of

many of the properties of living cells. Microchemistry has failed to show the differences in detail existing between living cells, although it has shown some of the more general differences and resemblances. Some other method of approach must be adopted for the study of such details.

This other method is to be found in one of the newest of the medical sciences—pharmacology, or the study of the reactions of living tissues to poisons. The importance of this method may best be shown by the citation of a few examples from an instructive paper by Arthur R. Cushny (*Lancet,* September 9, 1916). Thus, an accurate understanding of the toxicity of the saponins for different cells might give us the means for estimating the relative importance of the lecithins in the lives of these cells. The chemical properties of some poisons, such as acids and alkalies, are so simple as to suggest their modes of action and the nature of the substances upon which they act in the cells; they are less simple of others, such as quinine and hydrocyanic acid, but their general effects upon the ferments might be used to determine the presence and importance of these bodies in the cells. Finally the chemical actions of many of the poisons are still so obscure that we have no clear conception of them, but this fact does not deprive them of all importance as aids in the study of the properties of living matter.

As to these more obscurely acting drugs, their specificity of actions and the sharp limitations of these actions to certain structures lead to the conclusion that the cells upon which they act must have properties similar in one or more respects. Thus the affinity of the members of the chloroform and ether groups for lipoids is related to their properties of influencing the structures of the nervous system, and, conversely, they may be used to determine the presence of nervous tissues. Morphine and strychnine seem to be limited in their actions to nerve cells—bodies or synapses—therefore the material with which they react is sharply limited in its distribution in the body. There is a whole group of alkaloids which have actions limited for the most part to the extreme endings of the nerves, and some of these are further limited in their sites of action to the endings of the nerves of only one type. Thus epinephrine acts only on the sympathetic endings, but affects all of these, while ergotoxin is also limited to the same endings, but affects only such as have motor functions. The use of these two poisons, therefore, shows a similarity between the structure of all sympathetic endings and at the same time shows that the motor and inhibitory endings of the same system of nerves have definite differences. The illustrations might be multiplied, but enough has been said to show the importance, in the analysis of living matter, of the study of the actions of poisons upon the living cells.

In seeking to interpret the reactions of a drug upon several apparently diverse structures, Ehrlich postulated the existence of specific groups, such as the haptophores and toxophores which, respectively, attached the drug to the cells and then brought about its action. Such a conception must be rejected in the explanation of the differences in action of two allied simple chemical substances on the same structures, and it seems that in such cases, if not also in many others, the differences in action must be attributed to differences in the molecules as a whole rather than in the special affinities of their parts. The still newer field of colloidal chemistry may ultimately yield the explanations of some of the differences and similarities in actions between similar drugs upon the same structure and of the actions of a given drug upon diverse living structures.

Whatever may be the ultimate explanations of these reactions, there can now be no question of the great importance of the study of the action of poisons to the understanding of the nature of living matter. At present the only deficiency lies in the lack of appreciation of this importance.

METEOROLOGICAL FACTORS IN THE CAUSATION OF PNEUMONIA.

From the days of Hippocrates cold and damp were considered to be the moving factors in the causation of pneumonic conditions. Indeed, bronchopulmonary conditions have always been associated with cold to such an extent that the very word, cold, has come to be synonymous with a pathological condition affecting the respiratory passages. Yet scientific inquiry into the subject does not bear out this theory. While it is true that the months between and including July and October have the smallest proportion with about 4.5 per cent., the winter months have only a little less than twice that, or about eight per cent., while the spring months have the greatest share, about twelve per cent. While it is less prevalent near the equator, it is just as little prevalent near the poles. On the other hand, after exposure to the exhausting heat of the tropics the incidence of pneumonia has often phenomenal rises.

It seems that marked changes of temperature have more influence than either extreme, hence, probably, the greater prevalence in the intervening zone, where such changes are frequent. For the same reason it is common in great altitudes where the daily changes in temperature are likely to be marked. With respect to cold it is the prolonged exposure to low temperatures which, like prolonged

exposures to heat, depress and predispose to the development of pneumonia. Moderate degrees of cold seem rather to stimulate than to depress, hence the almost universal use of cold in the treatment of pneumonic conditions.

The factor of moisture seems to play even a lesser part than that of temperature, for during the months when humidity is highest, June, July, and August, there is the least pneumonia. The influence of cold and damp is specific, however, though indirect. During the months when this sort of weather is likely to obtain, there is usually considerable indoor congestion and overcrowding, with little or no ventilation, lack of exercise, and like conditions having a tendency to reduce vitality and make likely victims to bacterial invasion. Besides, according to Anders, under conditions of poor ventilation, there is an increased virulence of the organisms which cause pulmonary disease.

In the causation of pneumonia complicating other conditions, the same adverse and usually artificial environmental conditions operate. Wilson (*Archives of Pediatrics,* April, 1916) found that the pneumonia complicating measles had little, if any causal connection with season or weather. On the other hand, wherever there had been congestion and overcrowding, measles was more likely to be complicated with pneumonia. The incidence of pneumonia otherwise bore only an indifferent relation to cold and inclement weather.

THE HAY FEVER PROBLEM.

To the sufferer from the disease the hay fever problem is a momentous one in proportion to the severity of his attacks, which not only take the joy out of life during the season, but cloud the remaining months of the year with the anticipation of what lies before him. To the physician the disease is but one of the many unsolved problems, so far at least as its cure is concerned, and its prevention is as yet anything but an easy matter. So many are the victims of this distressful malady that they have organized into clubs and societies the better to study and combat their common affliction.

Hay fever follows on the presence of certain pollens, but pollens we have always had with us, though not hay fever. By the removal of the source of pollen the victim is cured, but this is not a simple matter, and, after all, the condition of the patient is by no means restored to normal, for it is certainly not normal to be hypersensitive to pollens whether these irritate by their mere physical makeup, or by their chemical constitution. Since subjects of the disease recover, or are better and worse in different seasons, and are relieved by traveling to another region which may contain similar weeds, it seems unlikely that chemical factors have much to do with the disease, while other data point to a general abnormal nervous excitability as the groundwork for the reaction.

Since the first description of hay fever, in 1819, humanity has been climbing to a pitch of nervous stress and strain which cannot from any point of view be called normal, and it is from those that ride the crest of the wave of culture and strenuosity that the hay fever army is recruited. Hay fever is therefore more common among women than men, among city than country dwellers, and among the educated and highly nervous than other classes. For the individual physician the combating of the tendencies of life which make for hay fever is certainly, in the language of Artemus Ward, "2 mutch," and yet the physician is frowned upon for his helplessness in the matter. Here is another problem, or rather a part of a more general problem, for a national department of health.

So far as the actual treatment of the disease is concerned, the destruction of the weeds producing the offending pollen in the neighborhood of large cities is to be considered, for pollen travels far. Local applications to the inflamed mucous membranes may keep the patient busy and make him feel that something is being done for his relief, but more experienced sufferers say that such treatment is either unavailing, or is like adding fuel to flame, as no foreign substance is more soothing to the sensitive surfaces than the normal secretion of the nose. Local anesthetics must soon be repeated and in larger dose, and are harmful in the long run, and vaccines seem to have more influence on the mind than otherwise.

The perfecting of the general health of the victim, between and especially preceding attacks, gives the best results, and often leads to a permanent cure by lifting him above the level of hypersensitiveness to the offending pollen.

USE OF OIL IN POSTOPERATIVE PERITONITIS.

At a meeting of the Société des chirurgiens de Paris, August 25th, Chaton (*Presse médicale,* September 7, 1916) described his method of using camphorated oil in laparotomies whenever septic foci were discovered. As soon as the abdomen is opened, the operator begins to pour in the oil and subsequently he adds to the quantity from time to time. When, finally, the abdominal wall is sewn up, after there have been a dozen or so respirations, protective compresses are arranged so as to absorb the excess of oil. The oil obstructs the lymphatic ducts, prevents

agglutination, allows of prolonged drainage, and possesses a tonic action on the heart. Ampoules containing from ten to twenty-five c. c. are used, and 300 c. c. of a one per cent. solution may easily be employed at one time. Chaton is greatly pleased with his results.

Obituary

ADONIRAM BROWN JUDSON, A. M., M. D.,*

of New York.

Dr. Adoniram Brown Judson, who died on September 20, 1916, was born in Maulmain, Burmah, where his father was stationed as a missionary, on April 7, 1837, and graduated as A. M. from Brown University in 1859. He then attended lectures at Jefferson Medical Colege. The Civil War breaking out before he had completed his course, he entered the navy as assistant surgeon in 1861, was promoted to passed assistant surgeon in 1864, and surgeon in 1866, resigning in 1868. At the close of the war he received the degree of M. D., 1865, from Jefferson Medical College, and in 1868 a similar degree *ad eundem* from Bellevue Hospital Medical College.

After several years spent in work connected with the health department of New York city, Doctor Judson devoted himself to orthopedic surgery, and in 1887 assisted in forming the American Orthopedic Association, of which he was vice-president in 1889 and president in 1890. For thirty years he was orthopedic surgeon to the outpatient department of the New York Hospital, resigning in 1908.

Doctor Judson was a man of lovable personality, prone to see that which was good in every man, and to overlook his failings. He was glad to extend a helping hand to the younger men in his specialty, and if he differed from his confrères on any topic, did so in a way that did not give offense.

Whatever Doctor Judson started to do, he did it with his whole heart, and he did it thoroughly. In nothing was this more clearly shown than in his connection with the New York Academy of Medicine. From 1886 until the time of his death, Doctor Judson was our statistical secretary, and to his diligence and painstaking accuracy we owe the exact record which we possess of the part which every Fellow of the academy has taken in its activities.

While chairman of the section in orthopedic surgery, he had full record made of the transactions of the section, and saw to it that these were published in full in many journals, both in this country and abroad, as well as being filed on the shelves of our own library, and in this, and many other ways, he made this section one of the most widely known throughout the medical world.

In his death the New York Academy of Medicine has lost one of its most faithful and conscientious officers, and in acknowledgment of his services the council of the academy desire this record of their appreciation to be spread upon the minutes, and copies sent to his family, and to the medical press.

*Communicated by the New York Academy of Medicine.

News Items

The Æsculapian Club of Philadelphia gave a reception in honor of the Physicians' Motor Club, Tuesday evening, October 3d, in recognition of their long continued active efforts for the rights of medical motorists.

Buffalo Academy of Medicine.—Dr. Joseph C. Bloodgood, of Baltimore, delivered an address on the Cancer Problem Based Upon Recent Experiences, illustrated with lantern slides, at a meeting of the section in surgery of the Buffalo Academy of Medicine, Tuesday evening, October 3d.

Women to Be Admitted to Membership in the Northern Medical Association.—At the last meeting of the Northern Medical Association, the second oldest medical organization in Philadelphia, it was unanimously decided on election to admit women physicians to membership in the society.

A Memorial to Doctor Peck.—It has been proposed to erect a research laboratory at the Philadelphia Hospital for Contagious Diseases as a memorial to the late Dr. Earl C. Peck, who was first assistant resident physician at the institution, and who died recently from anterior poliomyelitis.

County Societies Hold Joint Meeting.—Dr. Henry B. Doust, of Syracuse, was nominated president of the Onondaga County Medical Society, at a meeting held on the evening of September 26th, jointly with the Cortland County Medical Society. Other officers were nominated as follows: Vice-president, Dr. William F. Cregg, of Camillus; secretary, Dr. E. V. Sweet, of Syracuse; treasurer, Dr. R. J. Stoup, of Syracuse. The election will be held at the December meeting of the society.

American Röntgen Ray Society.—The following officers were elected at the annual meeting of this society, held in Chicago, September 28th, 29th, and 30th: Dr. Lewis Gregory Cole, of New York, president; C. S. Blair, of Chicago, and Dr. Howard E. Ruggles, of San Francisco, vice-presidents; secretary, Dr. William H. Stewart, of New York; treasurer, Dr. William A. Evans, of Detroit. Dr. James T. Case, of Battle Creek, Mich., was elected editor of the *American Journal of Röntgenology*, the official organ of the society.

The American Association of Obstetricians and Gynecologists held its twenty-ninth annual meeting in Indianapolis, September 25th, 26th and 27th under the presidency of Dr. Hugh O. Pantzer, of Indianapolis. Officers to serve for the ensuing year were elected as follows: President, Dr. John W. Keefe, of Providence, R. I.; first vice-president, Dr. Francis L. Reder, of St. Louis; second vice-president, Dr. Charles L. Ill, of Newark, N. J.; secretary, Dr. E. Gustave Zinke, of Cincinnati (reelected); treasurer, Dr. Herman E. Hayd, of Buffalo.

The Cartwright Lectures of the Association of the Alumni of the College of Physicians and Surgeons, Columbia University, will be delivered at the College of Physicians and Surgeons, 437 West Fifty-ninth Street, New York, Tuesday and Wednesday afternoons, October 24 and 25, 1916, at five o'clock, by Richard M. Pearce, M. D., professor of research medicine, John Herr Musser Department of Research Medicine, University of Pennsylvania, Philadelphia. His subject will be The Spleen in Its Relation to Blood Destruction and Regeneration. The public is cordially invited to be present.

Medical Association of the Greater City of New York.—A stated meeting of the association will be held in Du Bois Hall, New York Academy of Medicine, Monday evening, October 16th, at 8:30 o'clock. Dr. Fred H. Albee will read a paper on Experiences in War Surgery in France, which will be illustrated with motion pictures. Among those who will take part in the discussion are Dr. Augustin A. Crane, Dr. William Seaman Bainbridge, Dr. Clarence A. McWilliams, Dr. Foster Kennedy, and Dr. William B. Giles. First Lieutenant Charles D. Kayser, Medical Corps, National Guard, will read a paper on Paratyphoid Fever Among National Guard Troops on the Mexican Border, which will be followed by a general discussion.

The Bronx County Medical Society will hold a regular meeting on Wednesday evening, October 18th, at Ebling's Casino, 156th Street and St. Ann's Avenue, New York, under the presidency of Dr. John E. Virden. Dr. Thomas H. Curtin will read a paper on General Medicine and Eye Diseases and a paper on Some of the Important Causes and Symptoms of Mastoid Disease will be read by Dr. William M. Danning. There will be a general discussion.

Indiana State Medical Association.—The following officers were elected at the annual meeting of the association, held in Fort Wayne, September 27th, 28th, and 29th: Dr. John H. Oliver, of Indianapolis, president; Dr. John W. Phares, of Evansville, first vice-president; Dr. Charles M. Mix, of Muncie, second vice-president; Dr. George L. Guthrie, of Indianapolis, third vice-president; Dr. Charles N. Combs, of Terre Haute, reelected secretary-treasurer. Next year's meeting will be held in Evansville.

American Hospital Association.—Dr. Robert J. Wilson, of New York, was elected president of this association, at the eighteenth annual meeting, held in Philadelphia, September 26th to 29th, and other officers were elected as follows: Dr. Andrew R. Warner, of Cleveland, and Miss George M. Nevins, of Washington, D. C., vice-presidents; Dr. William H. Walsh, of Philadelphia, secretary; Asa Bacon, of Chicago, treasurer; trustees, Dr. Winford H. Smith, of Baltimore, Richard P. Borden, of Fall River, Mass., and Miss Mary L. Keith, of Rochester, N. Y.

Poliomyelitis in Neighboring States.—Up to the last available date of record there have been in New York city and the adjacent States of New York, Connecticut, Massachusetts, New Jersey, and Pennsylvania, the following number of cases and deaths: New York city, September 30th, 9,029 cases, 2,286 deaths; New York State, exclusive of New York city, September 14th, 2,785 cases, 318 deaths; Connecticut, September 18th, 677 cases, deaths not reported; Massachusetts, September 19th, 678 cases, 95 deaths; New Jersey, September 19th, 3,495 cases, 775 deaths; Pennsylvania, September 20th, 1,278 cases, 313 deaths; total, 17,935 cases, 3,787 deaths.

The Alvarenga Prize.—The College of Physicians of Philadelphia announces that the next award of this prize, which amounts to about $250, will be made on July 14, 1917, provided that an essay deemed by the Committee of Award to be worthy of the prize is offered. Essays intended for competition may be upon any subject in medicine, but must not have been published. They must be typewritten, and if written in a language other than English must be accompanied by an English translation. All essays must be in the hands of the secretary of the college on or before May 1, 1917. For full information regarding the conditions of the competition, address Dr. Francis R. Packard, secretary, 19 South Twenty-second Street, Philadelphia. The Alvarenga Prize for 1916 was not awarded.

To Amend the Public Health Law.—At a meeting of the governing body of the Medical Society of the County of New York, held at the Academy of Medicine on Monday evening, October 9th, it was decided to ask the next Legislature to amend the public health law by striking out Section 173, which reads: "This article shall not be construed to affect the practice of the religious tenets of any church." The action was the result of the recent decision of the Court of Appeals that reversed the conviction of Willis Vernon Cole, the Christian science healer, and granted him a new trial. In the opinion of George W. Whiteside, counsel of the society, who was present at the meeting, it would be useless to retry Cole because of the exception in the statute which prevents interference with any acts constituting part of the religious practices of any church. Mr. Whiteside said that under the existing law any persons desiring to practise medicine without having passed the necessary examination or undergoing the usual period of study would only have to organize some kind of a religious sect and meet in some building that might be designated as a church. All county medical societies in the State will be asked to cooperate with the local body in obtaining the passage of the amendment to the law.

The Eastern Medical Society of the City of New York held a stated meeting on Friday evening, October 13th, at the Hotel Brevoort. Dr. Joseph F. Saphir presented three cases of profound anemia due to ulcerated internal hemorrhoids. Dr. Maurice Fishberg read a paper on Traditional Fallacies About Tuberculosis, which was followed by a general discussion. A paper on the Treatment of Poliomyelitis was presented by Dr. Israel Strauss and Dr. P. W. Nathan, which was discussed by Dr. B. Sachs, Dr. Henry Ling Taylor, Dr. Percy B. Roberts, Dr. Leon Louria, and Dr. Henry W. Frauenthal.

Meetings of Medical Societies to Be Held in Philadelphia during the Coming Week.—Monday, October 16th, Clinical Association, Medical Society of the Woman's Hospital, Society of Normal and Pathological Physiology; Tuesday, October 17th, West Branch of the County Medical Society; Wednesday, October 18th, County Medical Society (business meeting), Section in Otology and Laryngology of the College of Physicians; Thursday, October 19th, Section in Ophthalmology of the College of Physicians, Northeast and Southeast Branches of the County Medical Society; Friday, October 20th, Jefferson Hospital Clinical Society.

Harvey Society Lectures.—The twelfth course of lectures given by the Harvey Society under the patronage of the New York Academy of Medicine, will be opened on Saturday evening, October 14th, with a lecture by Professor J. S. Haldane, of Oxford University, on the New Physiology. Other lectures in the course are: November 4th, Dr. F. M. Allen, of the Rockefeller Institute, the Role of Fat in Diabetes; November 28th, Dr. Paul A. Lewis, of the Henry Phipps Institute for Tuberculosis, Chemotherapy in Tuberculosis; December 16th, Professor Henry H. Donaldson, of the Wistar Institute of Anatomy and Biology, Growth Changes in the Mammalian Nervous System; January 13th, Professor E. V. McCollum, of the University of Wisconsin, The Supplementary Dietary Relationships Among Our Natural Foodstuffs; February 3d, Professor J. W. Jobling, of Vanderbilt University, The Influence of Nonspecific Substances on Infections; February 24th, Professor John R. Murlin, of Cornell University, The Metabolism of Mother and Offspring Before and After Parturition; March 17th, Professor Francis W. Peabody, of Harvard University, Cardiac Dyspnea; April 7th, Professor W. H. Howell, of Johns Hopkins University, The Coagulation of the Blood.

Personal.—Dr. Herbert Bruce, who is serving with the Canadian Army Medical Corps in France, has cabled his resignation as president of the Toronto Academy of Medicine, as he finds that he will be absent from Toronto for the entire winter. Vice-president Dr. John Ferguson has been elected president for the current Academy year, and Dr. D. J. Gibb Wishart has been elected vice-president.

Dr. Gwilym G. Davis, professor of orthopedic surgery at the University of Pennsylvania, has been elected to membership in the executive committee of the North American Children's Sanitarium, to fill the vacancy caused by the death of Dr. William L. Rodman. Dr. J. B. Carnett is chairman of this committee and other members are Dr. J. Torrance Rugh, Dr. De Forest P. Willard, and Dr. W. Blair Stewart, of Atlantic City.

Dr. William H. Davis, of Boston, has been appointed chief statistician, division of vital statistics of the United States Bureau of the Census. Doctor Davis was for a number of years chief statistician of the Boston Health Department.

Dr. Sidney D. Jones has been placed in charge of the Clinical and Röntgen Ray Laboratory at Fort Dodge, Iowa, succeeding Dr. Thomas H. Glenn.

Dr. George H. Whipple, professor of sanitary engineering at the Massachusetts Institute of Technology, has been retained by the New York State Department of Health as scientific adviser in the matter of the garbage nuisance on Staten Island.

Medical Director Philip Leach, of the New York Naval Hospital, has been assigned to duty as medical director of the Naval Hospital at Chelsea, Mass., succeeding Medical Director George B. Wilson, who died on October 1st.

Modern Treatment and Preventive Medicine

A Compendium of Therapeutics and Prophylaxis, Original and Adapted

THE THERAPEUTICS OF A PHARMACOLOGIST.

By A. D. Bush, M. D.,

Professor of Pharmacology and Therapeutics, University of Southern California.

Fortieth Communication.

PLEURISY.

In the plastic type of pleurisy the leading need is the relief of the sharp distress. For this purpose two measures seem feasible, counterirritation and some sedative of the opiate type. Counterirritation here assumedly benefits by increasing reflexly the circulatory exchange in the pleural area affected. Almost invariably in pleurisy, especially of the dry type, there are localized areas of tenderness in the skin. There may be in the immediate vicinity of the inflammatory process or as remote as the neck and shoulder, pleuritis of the costodiaphragmatic "accordeon pleat," often accompanied by distressing needle pricks in the skin overlying the acromion process. It is believed that these superficial areas of tenderness are due to the impinging in the posterior columns of the cord by nerve fibres from the inflamed area on other fibres from the cutaneous surface, and there ensues a contiguous irritation with receptive reference to the sensory distribution. For example, afferent fibres of the phrenic nerve are spinally contiguous with sensory fibres of the supraacromial; or, again, an intercostal nerve may supply both cutaneous and pleural surfaces. From all these data the reasoning is proposed, and corroborated in part by clinical experience, that superficial irritation of areas of skin tenderness will be followed by an improvement in the correlated affected area, the improvement being assumedly due to more rapid removal, through accelerated circulation, of the inflammatory products. But whatever may be the correct explanation, physicians usually find that sinapisms over associated areas of tenderness give remarkable alleviation in pleurisy.

For immediate relief an opiate may be demanded, and in a majority of cases the powder of opium will be found more efficacious than the principal alkaloid, possibly because of the synergism of the several narcotic principles; also, because of a peculiar though unexplained effect, which the salicylates often have in modifying inflammations of serous surfaces, it may prove advantageous to add some sodium salicylate to the powdered opium. Usually two or three doses of this combination prove adequate for controlling such distress as the patient feels unable to bear unaided; but its continuance is not advisable. Other effective measures during the period of convalescence are rest in bed, with limitation of the movements of the affected side.

Quinine has its advocates in the treatment of pleurisy, but its usefulness in this ailment may well be questioned. Possibly its former reputation as an antipyretic may account for the panacean value still ascribed to quinine by many practitioners.

In pleurisy with effusion further measures are demanded, and the summary of evidence indicates that little reliance may here be placed on the use of drugs. If the effusion becomes menacing, surgical interference, in the form of painstaking thoracentesis, is the chief recourse. Effusions of the milder sort are usually resorbed by the system, though some have to be aspirated ultimately. Various drugs and measures have been suggested at one time or another as accelerators of resorption, but the evidence as to their real efficiency is not convincing. The average physician probably thinks immediately of potassium iodide as the drug *par excellence* for promoting the absorption of exudates, but there is little in its known action to justify this opinion. To be sure, this drug will induce the resolution of syphilitic gummata, but this latter process has no analogy to the resorption of serous exudates. For this purpose probably no drug has any but remote and indirect action, such, for instance, as the salines have; but real dependence must be placed on nature or the surgeon.

Prophylaxis and Treatment of Arteriosclerosis.—Edwin W. Janes (*Northwest Medicine*, September, 1916) considers that prophylaxis should properly begin in childhood by teaching a fondness for adequate outdoor exercise, but the time when it will actually be begun will usually be in middle adult life. It should then comprise chiefly a moderation in diet, avoidance of worry and the securing of adequate exercise in the open. Alcohol and tobacco should be reduced, but their temperate use may be permitted. The treatment differs according to the conditions and to the underlying causes. Where there is hyperpiesis, every means must be employed to diminish nervousness and worry; exercise, graded to the patient's capacity, should be prescribed in the form of walking, hill climbing, golf, etc.; and a sharply limited general diet prescribed, with meat allowed only two or three times weekly, and fluids, salt and condiments greatly restricted. Treatment with the high frequency current does much to reduce excessive blood pressure, and its effects are fairly lasting. Where cardiac failure is manifest, digitalis is the drug of choice and may be used in small daily doses for months with much benefit. Apocynum cannabinum, in the form of the tincture, will sometimes give better results where there is marked edema. It may be given in a dose of one mil three times a day. Vasodilators should be used only as symptomatic remedies and calomel, salines and baths are of value in keeping down excessive pressure. Venesection may be used as an emergency measure, or it may be practised regularly about twice a year for its beneficial influence on blood pressure. In toxic arteriosclerosis, the source of the intoxication must be removed if possible and where syphilis is the cause this must be treated appropriately.

Treatment of Acute Poliomyelitis by Intraspinal Injections of Adrenaline Chloride.—P. M. Lewis (*Medical Record,* September 23, 1916) reports seventy-seven cases treated at the New York Nose, Throat, and Lung Hospital with adrenaline. There were eighteen deaths, of which only five, or 6.9 per cent., were due to straight poliomyelitis under the adrenaline treatment. The treatment was as follows: The bottle of one in 1,000 solution was placed in a bath of boiling water to drive off the .5 per cent. chloretone content, and the solution was used undiluted after cooling. The child's body was flexed over a six inch glass bottle to increase the interspinous spaces, the skin was painted with tincture of iodine before, and dressed with moist boric acid dressings after the injections. A medium sized aspirating needle was found to be the best and the punctures best made between the fourth and fifth lumbar vertebræ. Intraspinal pressure was relieved and two c. c. of the one in 1,000 solution of adrenaline was injected, repeated every six hours day and night uptil the temperature was normal, unless kept up by some cause other than the poliomyelitis. No local anesthetic was found to be necessary. Hexamethylenamine was given in moderate doses during the acute stage and any tendency to deformity was the signal for putting the affected limb in plaster of Paris.

Drainage by the Drop Method in Nephrotomy and Pyelotomy.—M. Devroye (*Paris médical,* August 12, 1916) points out that, although the initial mortality of operations on the kidney and renal pelvis is relatively low, the subsequent prognosis in these cases is uncertain owing to the possibility of a persisting lumbar fistula or of later infection of the kidney which may necessitate even nephrectomy. In a recent case of severe wound of the scrotal urethra in which cystostomy had been performed, and subsequently also pyelotomy for pyonephrosis, with introduction of two drainage tubes in the renal pelvis, Devroye was surprised to note that when dilute permanganate solution was run into the renal pelvis through one tube none of it returned through the adjacent outlet tube—the patency of which was known—but all through the cystostomy siphon tube in the bladder. This led to use of the ureter as the outlet tube in antiseptic irrigation of the kidney in three subsequent cases, with excellent results. These three cases comprised one each of pyonephrosis, pelvic calculus (with infection) and hydronephrosis After a pyelotomy, with evacuation of pus or stones, a Nélaton catheter (No. 12 or 14) with its tip cut off was pushed as far as possible into the funnel shaped transition from pelvis to ureter and fixed with a suture of fine catgut to the margin of the renal pelvis or adjoining tissues. All surrounding tissues were then sutured with catgut and the skin with silkworm gut or silk. An ordinary drain was left for two or three days in the renal fossa. After a nephrotomy, a catheter was similarly inserted to the ureter, through the kidney, and the latter sutured as usual round it. The patient having been returned to bed, sterile apparatus for irrigation by the drop method was at once connected with the catheter and the flow into the renal pelvis started. Solutions used comprised one in 8,000 or 10,000 potassium permanganate, one in 10,000 mercury oxycyanide slightly tinted with methylene blue, and in one pus case, the Carrel-Dakin solution, carefully neutralized with boric acid and diluted to five per cent. Use of a catheter in the urethra was found unnecessary, and also inadvisable owing to the probability of inducing cystitis. The solution was run through continuously at the rate of one drop every two seconds. The patients urinated more copiously than usual owing to the solution introduced, but were in no other way disturbed by the procedure. Aftercare consisted in daily renewal of the external dressing, generally soaked with urine from the drain in the renal fossa. In aseptic or slightly infected cases the irrigating catheter may be removed after three or four days; in intense pyonephrosis, after ten to fifteen days. When it is removed the drain may also be taken out and replaced with gauze wicks. Restoration of ureteral function is shown by cessation of urine extravasation on the dressing. Healing rapidly follows. The procedure is advantageous in that it combats infection by the natural route from kidney to urethra, antagonizes cicatricial narrowing of the ureter, and renders pyelotomy a less hazardous procedure than heretofore in comparison to the more mutilating nephrotomy. Its benefits are especially marked in renal infection—pyelitis, pyelonephritis, and pyonephrosis. Ascending infection is combated by it. The author's three cases ended in prompt recovery, with any tendency to fistula formation.

Appendicitis: A Record of Personal Experience in 1915.—Albert Ehrenfried (*American Journal of Surgery,* September, 1916) says that with regard to treatment of appendicitis after operation the patient is allowed water immediately upon request. Food is omitted for twenty-four hours, morphine being given sparingly when needed. After twenty-four hours, the patient is given broths, malted milk made with water, and orange albumin as desired, and a suds enema is administered. On the next day he is started on a diet of soft solids. If all goes well, he is allowed to sit up in a chair for half an hour on the fourth or fifth day, and thereafter for increasing periods. The stitches are removed on the eighth day, and adhesive strapping is applied over the wound. After drainage patients are allowed to sit up as soon as the temperature is normal, provided that the discharge is limited and the wound is well strapped. Right rectus incision patients are not allowed up in a chair until the stitches are out. The peritonitic cases have been treated by withholding food and water by mouth for forty-eight hours, maintainng the Fowler position, administering ten per cent. glucose solution in water by rectum in sufficient quantity and giving suds or milk and molasses enemata frequently as indicated. Recently, Ehrenfried has acquired the habit of using pituitrin to forestall or relieve distention, and he has given six or more ampoules in twenty-four hours in severe cases, always, it seemed to him, with benefit. He has not refrained, however, in cases of severe distention from using the time honored methods of stupes, drastic enemata and gastric lavage in the rare instances when they have been indicated. Moderate stimulation has been given when necessary, and morphine has been avoided.

Pneumococcal Meningitis. — A. Carnarvon Brown (*Lancet*, Sept. 16, 1916) records a specially severe case to show the strikingly favorable results obtained from the use of a stock pneumococcus vaccine. Lumbar puncture showed a thick, opaque fluid in which pneumococci were found. The first dose of vaccine reduced the patient's spinal muscular rigidity, diminished his delirium, and greatly relieved his headache. This dose was preceded by a second lumbar puncture, since the initial one seemed to afford some symptomatic relief. Each dose of vaccine also brought about a fall in temperature, which was delayed and temporary at first, but was fairly permanent after the third dose. In all, five doses were given and the patient made a complete recovery. The size of the doses used is not stated.

Intravenous Injections of Antimony in Ulcerating Granuloma.—George C. Low and H. B. Newham (*Brit. Med. Jour.*, Sept. 6, 1916) report that on the strength of the favorable experiences of South American workers with the intravenous use of antimony, they have employed this plan of treatment in a case of this refractory disease which came under their observation. After repeated administrations twice weekly for three and a half months the disease was cured. Antimony and potassium tartrate was used, dissolved in sixty mils of normal saline and given in doses beginning with sixty-five mgm. and increased to a maximum of 0.16 gram. No ill effects from the drug were encountered, although some general lassitude followed each injection. The use of x rays has also given good results in these cases and it is suggested that a combination of these two forms of treatment might hasten the cure. The condition is not affected by mercury or salvarsan, both of which were tried without benefit in the case reported.

Results of Disinfection and Early Closure of Wounds.—G. Dehelly (*Bulletin de l'Académie de médecine*, May 2, 1916) reports statistics from a military hospital in which Carrel's procedure of continuous wound irrigation, followed by early closure of the wound, was applied in the treatment of a series of forty-eight fresh wound cases. Of the seventy-six patients received in the hospital, four died of shock within a few hours, and twenty-four had simple fractures, contusions or other slight injuries, or bullet wounds, none requiring antiseptic treatment. The forty-eight cases treated by the Carrel method comprised wounds by shell fragments, grenades, bombs, or mines, all infected *a priori*,—an assumption proved valid by bacteriological examinations and the temperature charts. These forty-eight patients bore 155 wounds of which 135 were closed after antiseptic treatment, only twenty being allowed to heal spontaneously. Of the 135, 121 were closed before the twelfth day and eighteen between the thirteenth and the eighteenth days. As a result, 119 wounds, or 88.25 per cent., healed before the thirtieth day, eight more before the fortieth day, and the remaining eight, before the sixtieth day. Among twenty-two cases with fracture in which the procedure was applied, the results were precisely similar, eighteen healing within the thirtieth day. Comparison of these results with those obtained when wounds are allowed to close spontaneously, the majority of the latter requiring three months to heal, shows that by the new procedure the period of healing can be shortened by two thirds in over eighty-five per cent. of cases. Carrel's continuous antisepsis, where applied to the entire surface of a wound, completely eliminates lymphangitis and adenitis. The wounded region is slightly swollen, and remains supple. Neither muscular contractions nor rigidity of the neighboring joints follows. Osteomyelitis is also completely avoided, the bony surfaces being rapidly disinfected. Amputations for infection will, for the most part, disappear. Finally, the early wound closure obviates the thick, contracting cicatrices which follow prolonged treatment. The scar tissue not being required to fill spaces from which tissue has been lost, but resulting merely from the adhesion of normal tissues, remains flexible, does not obtrude in the intermuscular spaces, and consequently does not interfere with the functions of the limb.

Treatment of Cardiac Decompensation.—J. E. Benjamin (*Lancet-Clinic*, September 9, 1916) reports favorably on the use of powdered digitalis leaves in pill form in preference to other preparations of the drug. Three or four pills of average dose are given daily for two or three days. Where, in spite of rapid general improvement, edema does not lessen and there is no diuresis, a pill containing one grain each of digitalis leaves, squill, and blue mass often gives good results. Theophylline in five grain doses for three days acts well as a direct diuretic, not only often causing edema to vanish, but also ascitic fluid. For the early symptoms of acute heart failure, such as dyspnea and excitement, morphine acts extremely well when given hypodermically in repeated doses until the patient is quiet. In subjects with valvular disease who have had attacks of decompensation, but are continuing the various activities of life, often with dyspnea on moderate exertion as their only complaint, the author recommends the following:

℞ Tincturæ strophanthi, ...20 c. c.;
Tincturæ nucis vomicæ, ...40 c. c..
M. Sig. Fifteen drops after each meal.

Patients under this combination are very comfortable and their field of cardiac response seems increased. During convalescence from acute decompensation, the patient having progressed from massage, through passive and active motion, to sitting up and walking, the physician must impress forcibly on him the importance of remaining within this "field of cardiac response." Exercise tests to ascertain the cardiac reserve power should not be made according to any fixed rule. In one case, bending forward a few times; in another, merely sitting up in bed, and in yet another, climbing a flight or two of stairs may be the appropriate amount. The patient's exercise prescription must be based not only on results of these tests, but on a careful study of the pulse rate and quality, any change in the blood pressure, cough, dyspnea, precordial discomfort, giddiness, etc. In any case, orders as to exercise to be taken should allow less exertion than the functional tests indicate, as the present age is one of excesses and the patient is at to do more than he has been advised.

Operative Treatment of Flatfoot.—C. Arnd (*Correspondenz-Blatt für schweizer Aerzte,* August 19, 1916) cuts a groove on the posterior surface of the tuberosity of the scaphoid bone, releases the tendon of the tibialis anticus and transfers it intact to this groove. He asserts that the effect of this procedure is practically to shorten the tendon and enable it to pull the arch of the foot into shape. When the tuberosity is not sufficiently prominent the joint between the astragalus and the scaphoid may be opened, the groove cut within the joint and the ligament sutured over the tendon. The groove must be made deep enough to hold the tendon.

Treatment of Dislocated Fractures of the Long Bones. — C. Arnd (*Correspondenz-Blatt für schweizer Aerzte,* August 19, 1916) lays bare the fracture, makes a little notch in the end of the upper fragment in which he places a long stout nail with the point impinging on the upper part of the end of the lower fragment, which serves as a fulcrum. Then while the fragments are pulled apart traction is made on the head of the nail so as to use it as a lever to bring the fragments into proper apposition. When this is done the nail slants in a different direction than it did at first and is driven into the lower fragment. The head of the nail then acts to prevent the upper fragment from slipping out of place, the nail itself acts to prevent them from slipping from side to side, and the fragments are held together by the tension of the muscles.

Clinical Significance of Sinus Arrhythmia.—Leslie Thorne Thorne (*Practitioner,* September, 1916) says that the present war has demonstrated in numbers of cases that hearts supposed to be perfectly sound, and fulfilling their functions satisfactorily in the ordinary routine of life, have broken down entirely under severe and unusual strain. He is convinced that the presence of any kind of irregularity in the cardiac rhythm is not a normal condition and should not be disregarded. In many cases the only signs of abnormality are a slight cardiac dilatation and a marked sinus arrhythmia. The patients, usually young men, are apt to give a history of former heart trouble, such as a strain in school athletics, or an attack of rheumatic fever in childhood, and the cases of two young officers whose hearts broke down on active service are cited as examples. He concludes that the presence of sinus arrhythmia, which indicates an irregular cardiac dilatation, is not an absolutely normal phenomenon; that persons in whom it is present are more liable to suffer from a cardiac breakdown under mental or physical strain than are those who have a perfectly regular pulse; and that any soldier who has had a cardiac breakdown, and whose pulse shows evidence of sinus arrhythmia, is not fit for active service abroad. So far as treatment is concerned, absolute rest is not advisable, except in the acute stage of the breakdown. When the patient is able to get about at all, he should take as much walking exercise a day as he can without feeling done up. A course of mineral baths, and in some cases massage, is useful. Drugs seem to be of little or no use after a certain stage.

Injuries of the Urinary Tract.—Howard J. Williams (*Southern Medical Journal,* September, 1916) gives the following lines of treatment: In mild cases of kidney wounds, rest and ice bags locally, and conservative watching. In grave cases, with excessive shock and signs of intraperitoneal hemorrhage, or rapidly growing tumefaction in the loins, incision and suture of the kidney wound with drainage, or nephrectomy; if infection is present, incision and drainage or nephrectomy. In all cases use urinary antiseptics. In bladder wounds, open up and explore suprapubically. In extraperitoneal laceration close the bladder wound and employ a prevesical drain if possible; if not, use a suprapubic vesical drain. In intraperitoneal laceration, close the bladder wound and use peritoneal drainage. In all cases use a retention catheter through the urethra, and employ urinary antiseptics; in deep urethral wounds, perineal incision, with a catheter passed and retained in the bladder as in external urethrotomy, if the laceration is incomplete or partial. If the laceration is complete, perineal incision; find the ends of the divided urethra, suture the ends of the torn urethra over a permanent catheter passed into the bladder through the urethral canal, close the perineal wound with a superficial drain. In infection and perineal abscess or localized gangrene, try a free incision and multiple drains. In all cases use urinary antiseptics.

Bleeding Without Venesection.—L. Plantier (*Paris médical,* August 19, 1916) refers to the undeserved unpopularity of venesection as being due partly to its suggestion of an operation of last resort in the minds of patients and their families, and partly to the difficulty of carrying it out in stout persons with small veins and rapidly coagulating blood, as well as the realization of the possible dangers of sudden decompression from rapid bleeding. He deems superior the procedure he describes, which consists merely in leeching followed by cupping. Two groups of three of four leeches are applied, each group in a liqueur glass, some distance apart on the lateral aspect of the thorax or abdomen. The triangular, lacerated wounds produced by the leeches present a natural tendency, which is not possessed by linear wounds such as those made for wet cupping, to remain open and continue to bleed. Besides, the leeches secrete a principle which prevents coagulation, hence eliminating one of the difficulties presented in this connection by venesection in a certain proportion of patients. A flow of blood having thus been well established, Plantier removes the gorged leeches and maintains or accelerates at will the hemorrhage by applying cups alternately to the two groups of leech wounds, the cups being filled as often as is indicated by the total amount of blood to be withdrawn. An improvement in the technic is to use a cup with a suction bulb and a graduated receptacle for the blood below. By this method a bleeding is effected easily, regularly, progressively, and at any desired speed, while the possibility of a sudden, excessive drop in blood pressure or of congestion *a vacuo* is obviated. The patient readily submits to the procedure, which is thus rendered easily available in the nu-which is thus rendered easily available for the removal of toxic material from the circulation.

Sympathetic Ophthalmia. — J. H. Burleson (*Texas State Journal of Medicine,* September, 1916) treated a case of sympathetic ophthalmia in which the vision of the sympathizing eye was reduced to the ability to see large objects. A subconjunctival injection was made of thirty minims of mercury cyanide, prepared according to the formula of Dr. Emmett L. Jones, of Cumberland, Md. This was followed by a severe reaction, the side of the face being swollen so that the eye could not be seen for five days. This gradually subsided. At the end of one month the vision was 20/20 and the ophthalmoscope showed the media to be clear and the optic nerve head normal.

Tepid Baths in the Treatment of Malaria.— Theodore Zanger (*Lancet,* Sept. 16, 1916) found that half baths at 23° C. gave good results in the treatment of infantile catarrhal pneumonia. He tried their effects in a series of cases of malaria and obtained equally good results. The baths were given by filling the tub with enough water to half cover the patient and while he was lying in the water his arms, legs, back, and chest alternately were rubbed vigorously for five minutes. The baths completely stopped severe paroxysms and convalescent patient were soon restored to health with improved heart action and rapid decrease in their anemia. Usually the baths were given three times each week and in cases of recurrence as often as five to six times weekly.

Treatment of Tuberculosis in Infancy.—William W. Howell (*Boston Medical and Surgical Journal,* September 21, 1916) says that the object of treatment in these cases is to get the infants into such good physical condition that they can fight against any disturbing element absorbed from the primary glands, and to give the primary glands a chance to be walled off and become inactive, for they are never healed. The three factors essential in the treatment are rest, fresh air and sunlight, and suitable food. Rest is the most important, and by it is meant inactivity sufficient to get gain in digestion and weight. Though this stage is called chronic glandular tuberculosis, it is a fairly active process, and active tuberculosis needs rest. If later lung or bone tuberculosis needs rest, it is just as reasonable and necessary to give it at this stage. The rest should be persisted in till long after the symptoms have been relieved.

The Dressing of Septic Gunshot Wounds.— W. B. Davy (*Lancet,* Sept. 9, 1916) emphasizes as the result of a year's work at a base hospital, the undesirability of frequent changes of surgical dressings in the treatment of septic wounds. He advocates that the wound be carefully lined with a few layers of gauze containing tablets of salt which have been previously disinfected by immersion in tincture of iodine. After this dressing has been put in place and adequate drainage of the wound has been provided for, and all of its pockets have been laid open, the wound should be covered with several layers of absorbent material and firmly bandaged. The outside dressing, that is the absorbent material alone, may be changed as often as it becomes saturated with the discharges, and it may be kept from becoming foul by dusting with eupad or some other antiseptic. The inner dressing in contact with the wound surfaces should not be changed until it will come away easily without injuring the new granulations. It will be found covered with a layer of slimy pus, but this is the ideal medium for the growth of granulations and should be regarded with favor. As the salt tablets dissolve and the swelling in the wound declines, apposition of the surfaces will be helped by tightening the outer dressings. By this method all injury to the new granulation tissues is avoided as well as the pain and anxiety of change of dressings and the best conditions for prompt healing are provided.

Indications for Blood Transfusion.—E. S. Edgerton (*Jour. Kansas Med. Soc.,* Sept., 1916) considers that the majority of anemias offer indications for transfusion, depending upon their nature or severity. Anemia from gastric or duodenal ulcer, if severe with continued active bleeding, demands transfusion both for the hemostatic and for the nutritional value of the new blood. A less certain indication is found in typhoid hemorrhage, but transfusion has certainly given good results in some cases. A ruptured ectopic gestation sac is a certain indication for transfusion before, during, or after operation. The chronic anemias, other than pernicious anemia, require repeated small transfusions, and all forms of hemorrhagic diathesis are suitable fields for its use. Many surgical procedures are aided by transfusion, but shock seems to be helped least of all in this category. Among the essential blood diseases, pernicious anemia is often benefited more by repeated transfusions than by any other measure. Infectious diseases and various poisonings offers a fruitful field for this procedure, but its limited employment has not yet sufficed to determine its value.

Methods and Results in Surgery of the Stomach and Intestines.—George W. Crile (*Buffalo Medical Journal,* September, 1916) says that in cases in which resection of the stomach is indicated the reserve alkalinity is usually lessened, and often is reduced to a minimum. In these cases measures should be employed such as will obviate the further depletion of the body's stores of alkalies and bases, and the reserve alkalinity should be increased. Nitrous oxide is the anesthetic of choice. The acid producing effects of operative trauma should be reduced to a minimum by employing the technic of anociassociation. In resection the operation should be performed in two stages—first, gastrojejunostomy, second, resection after nutritional balance is restored. Water and subcutaneous saline infusions, glucose and sodium bicarbonate per rectum, increase the reserve alkalinity and consequently conserve the patient. Bromides per rectum conserve the patient by diminishing the transformation of energy, thus diminishing acid production, and by inducing sleep, the only means by which the damage done to the energy transforming organs by excessive acid byproducts can be repaired. The division of the stomach by the cautery and the searing of cut edges by moderate heat sterilize against pyogenic infections and against cancer growth, and prevents bleeding, three of the important considerations in gastric resection.

Miscellany from Home and Foreign Journals

Pain in Gastric Ulcer.—Harry Ginsburg, Isador Tumpowsky, and Walter W. Hamburger (*Jour. A. M. A.*, Sept. 30, 1916) cite the literature in full and record a series of experiments to determine the mechanism of the production of pain. The conclusions reached were that pain is due to increased endogastric tension through contractions similar to the hunger contractions which occur normally. The pain is also due to the hyperirritable state produced by the ulcer. Hyperacidity is not a direct cause of the pain, but may indirectly induce it to contract through stimulation of the stomach. Alkalies reduce the pain through neutralizing the acid and preventing its stimulant action. Pituitary extract causes increased contractions and increased pain, while amyl nitrite acts in an opposite way.

Syphilis as a Factor in Vague Stomach Disorders.—Cabot Lull (*Jour. A. M. A.*, September 30, 1916) shows with the aid of the x ray, the response to antisyphilitic treatment, and the Wassermann reaction, that a considerable proportion of gastric disorders is due to syphilis. There are three ways in which syphilis may cause these gastric disorders: First, through the presence of gastric gummas, erosions, or endarteritis; second, through structural changes in closely associated organs, either anatomically or functionally related to the stomach; and third, through direct action on the stomach of the spirochetes or their toxins without histological lesions. The cases in which the third mode of action occurs are those with the vaguest and most varied symptoms, and are often diagnosed as neurotic cases. This last group of cases may often show a negative Wassermann reaction until a provocative dose of salvarsan is given, indicating a latency of the spirochetes and suggesting their symbiotic existence in the tissues of the stomach and other portions of the body.

Differential Leucocyte Counts in Enteric and Dysenteric Convalescents.—I. Walker Hall and D. C. Adam (*Lancet*, Sept. 16, 1916) made a series of careful differential leucocyte counts in normal inoculated men and in inoculated men with infections by the enteric and dysentery organisms, in the hope of securing added means of differentiating between agglutination reactions in inoculated persons with and without active infection with enteric organisms. The content of agglutinins in antityphoid inoculated healthy men did not affect the ratio of polynuclear leucocytes to lymphocytes. It also was without effect upon this ratio in convalescents from infection with either paratyphoid organism. Where the agglutinins were due to inoculation the blood count was found approximately normal, but where they were due to infection, the typical leucocytosis or polynuclear leucopenia of the infecting organism was found. This observation not only proved of value in differentiating infective from inoculation agglutinins, but also suggested that there was a different mechanism of response of the human cells to living and virulent bacilli than to the killed organisms used in the vaccines for inoculation.

Child Weighing Twenty-five Pounds at Birth.—D. P. Belcher (*Jour. A. M. A.*, September 23, 1916) reports a child born at term, which weighed twenty-five pounds, measured twelve inches across the shoulders, and was twenty-eight inches long. The child was dead at birth. The mother was a multipara, thirty-five years old, five feet seven inches tall, and weighed 220 pounds. The circumference about her hips was fifty inches. Labor was difficult and prolonged and special trouble was encountered in the delivery of the shoulders. There was only slight perineal laceration. The child was a girl.

Renal Calculi in Rudimentary Kidney.—Ferguson Lemon (*Archives of Radiology and Electrotherapy*, September, 1916) reports a case in which six renal calculi were found in a nonfunctioning rudimentary kidney or vestigium of the Wolffian duct. Several x ray pictures had been taken and a negative report made. In spite of the negative x ray findings the patient was operated on for a floating kidney. He made a bad recovery from this operation and the attacks of pain were more frequent. Later, the nerve was severed but the pain still continued. Doctor Lemon saw the case later and his x ray plates showed the presence of six shadows in the right lumbar region close to the crest of the ilium. The patient was subsequently operated on and the stones were removed. He remained free from attacks for about two weeks, when another severe attack of pain set in. A further x ray examination showed evidence of a concretion in the appendix and the latter was removed. The patient is considerably improved, but still complains of occasional pain in the same area.

Prolonged Hyperpyrexia in a Child with a Mid-Brain Tumor.—C. Violet Turner (*British Journal of Children's Diseases*, September, 1916) calls attention to the case because of the duration of the hyperpyrexia. High fever is seen commonly as the terminal manifestation of cerebral lesions in children, and extreme variations of temperature are also noted in meningococcal meningitis, middle ear disease, and other infectious intracranial conditions. For ten days the temperature would reach 105° to 107° F., once or twice every twenty-four hours and then fall to subnormal within eight to twelve hours. The highest temperature recorded was 109° F. axillary and 111° F. rectal. Four hours after this temperature was recorded it had fallen to 100° F., and in eight hours it was subnormal. The rises occurred most frequently at 11 p. m., but this was not constant. The pulse varied with the temperature. The respiration rate also showed corresponding variations, and just before the patient died the respiration was of the Cheyne-Stokes variety. After death, a solid rounded tumor was found situated in the midline in the region of the corpora quadrigemina. Microscopically the tumor consisted of numbers of round cells, uniform in size, with but little intercellular matrix. In parts the growth had undergone cystic degeneration, leaving a hyaline material without cell elements.

Gastroenteritis Due to Bacillus proteus.—W. Boxwell (*British Journal of Children's Diseases,* September, 1916) gives the history of an interesting patient, who had a sudden attack of gastroenteritis with sharp hemorrhage from the bowel. High fever and delirium were present, there was pain in the muscles and joints similar to that found in Henoch's purpura. Later, transient paralysis of different limbs was observed and the fever chart showed a hectic fever long protracted. The blood culture was negative, but the culture from the feces showed a bacillus similar to Bacillus proteus. Vaccines were made and injected into the patient. There was considerable reaction after the first injection which was of five million, a milder reaction after the second of ten million, and a slight reaction after the third of fifteen million. The dose never exceeded twenty-five million and was given once a week. Recovery was complete.

Chronic Multiple Arthritis.—George R. Elliott (*Medical Record,* September 23, 1916) divides the condition into two types, the proliferating or ankylotic, and the degenerative or nonankylotic. The ankylotic type, called either rheumatoid arthritis or atrophic arthritis, usually attacks the young adult, has an irregular and frequently overlooked febrile onset; the best external signs are in the small peripheral joints which tend to become fusiform, it is steadily progressive. If ankylosis tends to occur, the patient becoming bedridden may live for years, dying of cardiovascular renal disease with anemia. This type is generally admitted to be due to an infection. The theory of nerve origin of rheumatoid arthritis is now practically dropped, and most authorities agree that the cause is a bacterial infection, many alleging a variety of infecting organisms especially of the streptococcus group, while others think that there will ultimately be found a single causative organism.

New Urinary Test of Prognostic Value in Pulmonary Tuberculosis and Diagnostic Value in Typhoid Fever.—Petzetakis (*Bulletin de l'Académie de médecine,* August 8, 1916) describes a test which he terms the iodoreaction, which consists in adding to the urine a solution of one part of iodine and two parts of potassium iodide in 200 parts of water, or preferably, a five per cent. solution of iodine in alcohol. Fifteen or two c. c. of filtered urine are placed in a test tube and two or three drops of the reagent dropped over its surface. By gently tapping the tube, these drops are mixed with the upper two c. c. of the urine, and the mixture watched for a time. If no change of color appears the test is negative; if positive, the upper portion assumes a yellow color. Dark urines should be diluted before testing. If doubt as to the result of the test is felt, a drop of a very dilute solution of sodium thiosulphate or a few drops of urine is added to the upper portion, causing the suspicious color to disappear in case of a negative reaction, and accentuating or not affecting it in case of a positive reaction. The test remains valid in the presence of albumin, sugar, acetone, ether, benzine, toluol, and practically all coal tar analgesics, as well as upon heating. Cryogenin and neosalvarsan, however, sometimes impart the yellow tint. In normal subjects the test is always negative. In lung tuberculosis it is seldom positive at first, but was uniformly positive in eight advanced cases. Among fourteen cases of tuberculous pleurisy, nine were positive. Of thirty-three tuberculous patients yielding negative reactions, none died, whereas of twenty-one patients yielding strongly positive tests, fifteen died within two to six weeks. Thus, in tuberculosis, a positive iodoreaction is of unfavorable prognostic significance. In fourteen cases of typhoid fever the reaction was uniformly positive, appearing within the first five days in nine of these, i. e., before the Widal reaction itself. It also sometimes preceded the diazo reaction or existed where the latter was absent. The test was also positive in two out of eight cases of influenza, two of scarlet fever, one of erysipelas, and one of puerperal fever; in each of these cases the diazo and Moriz-Weisz tests were likewise positive. The simplicity of the reagent used in the iodoreaction is a marked advantage over other similar tests for bedside use.

Location of Foreign Bodies in the Fingers.—Roscoe C. Webb (*Jour. A. M. A.,* September 30, 1916) demonstrates a method by effective transillumination of the finger, which can be made simple by the following procedure. A piece of black woolen cloth eight inches square is backed with a piece of adhesive plaster of the same size, and through the centre an oval opening five eighths by one half inch is cut. This cloth is then placed over an electric light, with a reflector, and the finger to be examined is laid over the hole in the cloth. By making pressure over the suspected area with a pointed instrument the foreign body can be brought out clearly, and more so if the finger is made bloodless. The finger may be placed over the opening during the operation and the object may thus be accurately located and removed.

Crossed Hip Reflex in Enteric Fever.—E. B. Gunson (*Lancet,* Sept. 16, 1916) reports that this reflex is elicited by firmly grasping the body of the quadriceps femoris above the knee and pinching it between the thumb and fingers. This produces some pain at the site of grasping and the reflex consists in the flexion of the hip and extension of the great toe of the opposite side. An incomplete reflex may occur with only one of these two movements taking place. The pain elicited by the stimulation is marked and usually persists for several days after the reflex movements cease to develop. This reflex, either complete or incomplete, appeared in a considerable proportion of the enteric fever cases in which its presence was sought, occurring as early as the second day of the disease and lasting to as late as the eighth week. It was not found to bear any direct relation to the severity of the disease, but did tend to be more marked and persistent in the more severe cases. Along with this reflex others, such as the knee jerk and abdominal reflexes, were usually diminished or absent. These findings were taken as indicative of some temporary disturbance in the function of the spinal cord and their occurrence seemed to be of some diagnostic value. The crossed hip reflex was also found in cases of brain tumor, various cerebrospinal conditions, and diphtheria.

Fatality Following Acute Otitis.—I. W. Voorhies (*Medical Record*, September 23, 1916), in reporting a case of death following a mild otitis, remarks that the appearance of the drum may be misleading and that a culture should be taken in every case. Further, any abrupt cessation of discharge with unilateral headache indicates a condition requiring operation, and no patient with acute otitis should be allowed to escape from trained observation until the condition is entirely cured.

Vaccination of Guineapigs with Bacillus aerogenes capsulatus.—Muriel Robertson (*Lancet*, September 16, 1916) undertook experiments to determine whether or not immunity could be produced by the prophylactic inoculation of Bacillus aerogenes capsulatus. The results showed conclusively that no immunity could thus be produced, in guineapigs, at least. And, further, that in these animals the survival of one infection with this organism did not confer any immunity to the injection of an infecting dose at a later period.

Case of Intrauterine Scarlet Fever.—R. M. Liddell and C. E. Tangye (*Brit. Med. Jour.*, September 16, 1916) report the case of a mother, exposed to scarlet fever near term, who gave birth to a normal, living child which, however, was found to be desquamating freely on its body and extremities. The infant's urine also contained traces of albumin. The child made an uneventful recovery. During the last week of her pregnancy the mother complained of a "burning pain inside" but was otherwise entirely normal. She was immune to scarlet fever as the result of an attack in childhood.

Glandular Carcinoma of the Uterus in a Child Aged Two and One Half Years.—Joseph E. Adams (*British Journal of Children's Diseases*, September, 1916) states that for three weeks before admission to the hospital the child had a bloody flow from the vagina which had increased in amount and frequency. There was no pain, but a fullness had been noticed in the child's abdomen. There was no family history of carcinoma. On examination, a palpable tumor partly cystic in consistence, was revealed in the hypogastrium, situated between the bladder and rectum. A catheter specimen of urine contained no blood. At operation the rectovesical space was found to be occupied by a cystic growth about the size of half a tennis ball. The growth obscured the position of the uterus, but was obviously attached to the roof of the vagina. It was too adherent for complete removal. The child died two months later. At autopsy, a large growth completely covered by peritoneum, adherent to the posterior surface of the bladder and closely connected with the rectum posteriorly was found. Several enlarged mesenteric nodes were removed for examination. The vaginal report showed the specimen to consist of the uterus and its appendages. The body and cervix of the uterus were largely replaced by the breaking down growth. The microscopic diagnosis was carcinoma with both columnar and cuboidal cells, having a somewhat tubular arrangement. It belonged to the group of carcinomata arising in the glandular epithelium of the body of the uterus.

Syphilitic Reinfection.—D. Villanova (*Revista de Ciencias Medicas de Barcelona*, July, 1916) reports two cases of supposed reinfection. One was not a clear case, but was probably a chancrelike mucous patch with accompanying adenitis, but the other was an undoubted case of reinfection of a man from his wife after several years of apparent cure. Villanova insists, however, that such cases are rare and the history and physical examination should be gone into thoroughly before making a diagnosis of reinfection.

The Effect of Trench Warfare on Renal Function.—J. W. McLeod and P. Ameuille (*Lancet*, Sept. 9, 1916) summarize the results of their studies: That exposure alone has nothing to do with the production of a large number of the cases, especially of the milder ones; that if it plays a part in the severer cases this is similar to that played in many infectious diseases, that is, it causes a defective circulation and diminished resistance in the kidney; that a transitory albuminuria is very common in the troops undergoing severe physical strain, and that finally diet seems to be the most plausible explanation of the transitory albuminuria and mild nephritis, and also is a contributory factor in the more severe cases. To substantiate this conclusion, the authors point out that the average soldier takes protein food in excess of his requirements, throwing an added strain on his excretory organs, that the large number of cases of gingivitis indicate the effects of a restriction in fresh vegetable foods, and that, finally, there is evidence of the existence of a slightly scorbutic condition prevailing among the men. This scorbutic condition reduces the resistance of the kidneys along with its effects upon other organs, and the former give out when added demands are made upon them by the excess of protein in the diet or by bacterial invasion of the body.

Hereditary Factor in Pellagra.—C. B. Davenport (*Archives of Internal Medicine*, July, 1916) adduces evidence that while the disease is not inheritable in the same sense as is a brown color of the eyes, its course depends on certain constitutional, inheritable traits of the patient. Pellagra is probably communicable, as suggested by the careful research of E. B. Muncey, whose article follows that of Davenport. When both parents are susceptible to the disease, at least forty per cent. of their children are likewise susceptible; the significance of this is accentuated by the fact that pellagra affects less than one per cent. of the population in the region studied by Muncey. That susceptibility is, with infection, also an important etiological factor is evinced by the varying reactions to the toxin of the disease shown in different families. Thus, many families never show mental symptoms, while others usually do. In some families intestinal symptoms are slight; in others, severe and rapidly fatal. In some the skin eruptions are but slightly marked; in others, severe ulceration and dermal desquamation are characteristic. The fact that among affected children there are brothers and sisters who have never shown pellagra symptoms can be understood as due to inheritable constitutional differences, just as brown eyes and blue eyes occur in same family.

Proceedings of National and Local Societies

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held October 5, 1916.

The President, Dr. WALTER B. JAMES, in the Chair.

The Management of Poliomyelitis with a View to Minimizing the Ultimate Disability.—Dr. ROBERT W. LOVETT, of Boston, read this paper, which appears in abstract form on page 747 of this issue of the JOURNAL.

Dr. SIMON FLEXNER said that Doctor Lovett's most excellent paper should properly be discussed, not by a pathologist, but by an orthopedic surgeon, from the point of view presented, though it was a pleasure to him to be asked to open the discussion because he had followed with interest the work of Doctor Lovett in Boston and Vermont, where he had carried into effect principles and methods of aftercare of the paralyzed that appeared to be an improvement over older methods of treatment. Doctor Lovett had based his views on the pathology of the disease, which was the logical way to approach the subject; and he had done the speaker the honor to employ in his descriptions conceptions and explanations for which the studies of the speaker had been responsible.

The basis of the modern conception of poliomyelitis was that it was an infectious disease in which the paralysis was merely an incident and an accident and by no means a necessary part. The percentage of cases in which paralysis occurred was probably much lower than had been previously believed. Had the pathology of the disease been worked out originally in artificially infected animals, this confusion would never have occurred. Nevertheless, Wickman had discovered clinical types of the affection in which paralysis never occurred; but experiments on animals and the employment of lumbar puncture both showed that, whether or not paralysis occurred, changes took place in the cerebrospinal membranes and fluid which indicated implication of the meninges in the pathological process.

In many cases, there was no invasion of the substance of the brain and spinal cord. When invasion did take place, it was through the lymphatic structures about the bloodvessels which became infiltrated with cells—usually of lymphoid type. In a proportion of cases the process went no further; but it was common that when so much involvement had arisen, actual infiltrations occurred in the nervous tissues, the gray matter of the cord especially, but also, in far less degree, the white matter; and not only the anterior gray matter of the cord, but the posterior also and the intervertebral ganglia which were among the earliest structures to show lesions.

The infiltrative process damaged the nervous tissues and thus interfered with function in two main ways; the cellular invasion of the sheath of the bloodvessels obstructed the lumen and reduced the flow of blood; the cellular and fluid exudate pressed in the nerve cells and fibres. In this way alone disturbance of function leading to paralysis of muscle groups might be produced. This class of pathological changes was subject to complete reversion. Once the infectious process was arrested, as it was by the developing immunity principles, resolution of the exudate took place and function was restored. This change was noted clinically, and frequently, in cases in which paralysis of members disappeared in a few days or weeks. Another more severe lesion, however, might occur. The virus of the disease might attack and seriously injure or actually destroy nerve cells. When the cells of the anterior horn were thus injured and became neurotic, they were quickly invaded by phagocytes which brought about their disintegration. This process was not reversible; its effects were therefore permanent. Commonly, the two classes of changes were united in one person, so that partial but not complete recovery of function took place.

The muscles presided over by the lost nerve cells were for the time being paralyzed. The theory on which Doctor Lovett proceeded in this instance was to reeducate the nervous system in such a manner as to open new paths along which impulses might pass from the brain to the muscles. On account of the many connections between neurons, there would not seem to be anything anatomically impossible involved in the concept. The proof must lie in the results achieved by the educative methods described

One word in conclusion: The pathological processes being what they were, tended to reversion. Hence, recovery was the outcome to be looked for and expected, its extent being determined by the degree of the reversionary process to which the paralysis was due. Hence, any form of treatment, not distinctly prejudicial, would be followed inevitably by some improvement. This improvement tended to occur during the early weeks or months following the attack; the paralytic residue, after this process was exhausted, was that attributable to more severe injury or destruction of nerve cells. The restoration of this further loss of function, when it was accomplished, might be the result of the reeducative methods which had been described.

Dr. E. C. ROSENOW, of the Mayo Foundation of Rochester, Minn., said that in discussing Doctor Lovett's paper, it would be useless for him to do so specifically because it bore largely on therapeutics, a subject of which the speaker knew little. However, some of the experimental results Doctor Rosenow had achieved bore directly or indirectly on the management and treatment of poliomyelitis. Dr. E. B. Towne, Dr. G. W. Wheeler, and he himself had studied the present epidemic, both in Rochester, Minnesota, and here in New York at the New York Hospital, from the standpoint of the elective localization of the bacteria (chiefly streptococci) isolated from the throat, from the tonsils, and from lesions of the central nervous system. The technic used was similar to that employed by the speaker in studies on the elective localization of bacteria in various other diseases, including diseases of the nervous system.

The tonsils, especially in patients over three or four years of age, yielded on pressure a surprisingly large

amount of infectious material, even in patients with no subjective or objective signs of acute tonsillitis. In all of seventeen cases where tonsils were removed after death and carefully sectioned, there were found from one to fifteen peculiar areas of localized necrosis, usually at the base along the capsule not communicating with the surface. They contained a peculiar, opalescent material chiefly filled with large and small mononuclear cells, polymorphonuclear leucocytes, and often large numbers of diplococci of the usual size and occasionally some small forms; fusiform bacilli and micrococci. In three or four adenoids removed at autopsy similar pockets were found. The ages of these patients ranged from seven months to twenty-four years.

The importance of localized foci of infection in the tonsils as a point of entrance of bacteria in poliomyelitis had not been specifically emphasized. Owing to the presence of large numbers, and often in almost pure form, of a streptococcus which on injection produced paralysis in animals, rabbits, guineapigs, dogs, cats, and monkeys, and to the low virulency of the bacterial flora in these patients, the experimenters felt with Doctor Roper that tonsillectomy was justified in patients in whom there was persistence for some weeks of fever, irritability, lack of appetite, and little or no improvement in the paralysis, or in whom the paralysis was slowly extending. This had been done under light ether anesthesia in eleven cases. In none of the cases subjected to tonsillectomy had there been any sign of acute tonsillitis. In most of them there was found a surprisingly large amount of pus and infectious material during the tonsillectomy. Numerous cross sections of the extirpated tonsils revealed pockets similar to those in the fatal cases, but which were smaller and fewer in number. None of the cases were made worse. Most of them showed improvement soon after tonsillectomy and in several the results were strikingly favorable, the fever disappearing, the extended paralysis being arrested, and the general condition greatly improved.

In the light of these facts, it was possible that unrecognized foci in the lymphoid tissue of the throat was an important factor in determining the severity of the initial paralysis, especially in preventing the usual early improvement, the localized foci affording entrance way to the organisms having elective affinity for the central nervous system. The number of cases of tonsillectomy were of course too few to warrant drawing positive conclusions; the results were merely suggestive. The experiment had proved, however, the presence in the throat, in the tonsils, and in the central nervous system, in epidemic poliomyelitis, of a peculiar streptococcus which, when injected into animals, including the monkey, produced a flaccid paralysis due to lesions in the central nervous system.

Dr. Frederick Tilney said that Doctor Lovett had shown how much could be done in the intelligent aftercare of cases of poliomyelitis. Certain details in his paper interested the speaker, who thought stress should be laid on these, so he would confine his remarks to them. In most severe cases of poliomyelitis, it was generally admitted that there was a focus of intensity in the inflammatory process. The situation of this focus in the central nervous system determined the distribution of the most profound motor defects and the most persistent residual paralysis. This focus was usually accompanied by a more extensive involvement, characterized by less extreme degree of inflammatory reaction which determined the recessive paralysis. It was probable that there were no means at present to combat the intensity of the focus or its accompanying involvement during the acute stage of the disease. Experience with the serum treatment indicated that it might be beneficial in the preparalytic stage and possibly in the ascending, bulbar, and meningitic forms.

The first object, therefore, in limiting the resulting disability, was to determine as nearly as might be the exact position of the focus of intensity in the central nervous system in order to deal with what was certain to be the most persistent and profound residual paralysis. This determination was best made by means of electrical reactions which, for this reason, assumed great importance, not only in the diagnosis and prognosis of the disease, but also in its treatment. These reactions should be taken at the beginning of treatment.

Knowing the groups of muscles most affected, it was next necessary to guard against the development of malpositions in the limbs. This was particularly true of foot drop, shoulder drop, and knee back. Care should be taken that the bed clothes put no undue pressure on the foot. Sand bags might be used to prevent overextension of the knees, and pillows, foot boards, and plaster of Paris splints met the tendency toward podoptosis.

The question naturally arose at what time it was best to begin treatment. The most conservative attitude put the earliest beginning of treatment at the end of six or eight weeks, but those who took a more radical position affirmed that treatment should be begun as soon as the fever disappeared. The latter was dangerous because it favored further spread of the infection, and the former was unnecessarily cautious because much time was lost which might be used advantageously in the application of beneficial therapeusis. It was safe to say that treatment might advantageously and safely be begun at the end of the third or fourth week, but in cases with pain and tenderness it should be undertaken most cautiously and at once be given up if the pain tended to increase.

The principal elements of the treatment included active and passive exercises, massage, support, and electricity. This referred to immediate aftercare and did not include surgical necessity.

The value of electricity had been much questioned, owing undoubtedly to its improper application. It was certainly true that electricity, properly applied in this disease, had a real value. The faradic current should not be used for two reasons: First, because it caused no reaction in profoundly paralyzed muscles, and, second, because it tetanized partially paralyzed muscles and thus fatigued them. The ordinary galvanic current was also ineffective. The most useful form of electrical current was the sinusoidal galvanic, which not only produced rhythmical contractions of the muscle groups involved, but caused alterations in the polarity of the current. To get the best effects of the electrical treatment, the part to be stimulated should be first

massaged. The effects might be further enhanced by applying heat to the surface, by means of either a hot pack or a calorescent lamp. In this way about one half of the current strength might be employed to effect efficient muscular contraction, whose production might otherwise require current strength sufficient to cause pain, which raised a serious obstacle to this treatment, especially in young children. The electrodes should be static and not moved about. They should be fastened firmly in position over the muscles to be stimulated. A towel, wrung out of warm salt water, should be placed between the skin and the electrode. The current should never be started at the maximum, but gradually increased during the treatment, which should last fifteen to twenty minutes. Massage, as well as the electrical treatment, should be given daily. It was even better if the massage could be given twice daily. Exercise might be recommended at the end of the third week and should be confined to passive movements of a mild sort. During the fourth week the child might be placed in a bath tub filled with warm water for fifteen or twenty minutes each day. The addition of salt rendered the water more buoyant, so that while in the bath the child was able to make voluntary movements in the paralyzed limbs which was impossible under other circumstances.

From the end of the fifth week special exercises should be devised to meet the special defects in the musculature. In leg cases, a very valuable contrivance was a skate which ran upon a track. The patient sat on a chair and, putting the foot on the skate, moved it back and forth. If the muscles were not strong enough for this motion, strings running over pulleys could be attached to the heel and toe so that with the aid of a hand the patient exercised the limb. Muscular individualization and substitution should be begun under special instruction and much could be accomplished in this way.

Splints, braces, plaster of Paris casts, and various other forms of support were never curative in their application and should be advised only when malpositions of the limb threatened to do injury to the joint, or caused undue stretching of a paralyzed muscle.

Exercise, in the speaker's opinion, was, above all other things, the most essential factor in the after-treatment of anterior poliomyelitis. This might be beneficially supplemented by massage and properly applied electricity. All of these means constituted the type of treatment to which every case was entitled; but without persistent application for a long period of time, no patient could be said to have had full opportunity for completely normal restoration.

Dr. Charlton Wallace said that every one in New York who had children suffered during the last few months with hysteria, for they confronted a disease which they did not know how to control. It was not the speaker's intention to talk about the etiology or pathology of poliomyelitis, as that had been done very lucidly by others, but to call attention to the fact that from an orthopedic standpoint each case of infantile paralysis presented a separate study, and it was observation of the muscular anatomy and the physiology of those muscles that enabled them to care for a case properly. It was well to beware of the haphazard treatment by those untrained and unskilled in the anatomy and physiology of the muscle groups.

Treatment should be started when the acute stage had subsided, but there was a question as to when the acute stage ceased. It was the speaker's opinion that it lasted only so long as there was any inflammatory process in the spinal canal. The acute stage lasted so long as there persisted tenderness of the joints. No treatment, except absolute rest, should be given other than the serum treatment during the acute stage and application of plaster of Paris bandages to the feet to prevent foot contractures, After that, orthopedic treatment should be started. There had been patients with tenderness in the joints lasting from three to four months; such patients should be kept in bed in a horizontal position. A plain wooden bed, with a mattress, was excellent for this purpose. Orthopedic treatment should not be carried out without general hygiene, fresh air, sunlight, proper food, etc.

In regard to braces, the speaker believed that no patient who had paralysis of the lower extremity or back should go about without brace support. Braces were used, in the first place, to prevent deformity and strain on affected muscles. They also prevented the strong muscles from overacting. Braces also helped in the physiological function of walking, which should be encouraged as soon as the patient was able to sit up and get about.

Another valuable aid was muscle training while there was power in the muscle; but the warning should be given to the parent that this would not cure, but was an aid only toward restoration of normal power. The speaker had seen instances of muscle training improperly taught, where the parents, having believed this would cure the child, set aside all braces, resulting in the worst types of deformity. The cases benefited by this method had been properly handled. Massage played some part and electricity might be of some benefit. While there was a possibility of improvement, every aid that could be given without harm should be utilized, and therefore it seemed that these children should wear braces, receive muscle training, massage, and some electricity.

Operative treatment should not be resorted to until three, four, or five years had passed, except when contractures and deformities existed, which should be overcome so that the patient might walk with supports. Some forms of operation were more appealing than others; a dangle foot, for instance, might be operated on perhaps within two years, or two and a half years after onset. The procedure preferred for these feet affections was the removal of the astragalus, displacement of the foot backward, and the transplantation of the selected tendons. The speaker had seen several hundred of these cases have circulation so restored after operation that the warmth of the foot was greatly increased and a good base was obtained for standing and walking.

Dr. G. R. Pisek was inclined to disagree with Doctor Lovett in his statement that he was presenting nothing new this evening. It must be gratefully acknowledged that his scientific method of muscle

testing would add valuable facts to the conception of poliomyelitis and place the treatment on a more rational basis. Doctor Lovett had brought a note of optimism to the situation, an optimism based on results obtained and recorded, and in the opinion of the speaker he had proved his case. The pediatrist had a duty to perform as well as the orthopedist, whose viewpoint had been ably expressed by Doctor Wallace. The pediatrist was mainly concerned with the acute and convalescent stages of poliomyelitis and with the opportunity for study afforded by the epidemic and in cooperation with other members of the medical profession, and it should be his duty to correlate all the facts in his possession so that diagnosis could be made more certain early in the disease. Upon the pediatrist devolved the task of sifting out the large mass of data gathered during this epidemic, particularly from the clinical standpoint, establishing, if possible, a symptomatology for the acute stage. Seventy per cent. of the cases were easy to diagnose; the other thirty per cent. were not so readily diagnosticated, while the so called abortive or nonparalytic types were baffling in the extreme.

Another duty lay in the analyses of the great number of cases observed this summer so that a rational basis for treatment could be established. It was certainly necessary to decide what was the proper method of handling the acute stage. Serum treatment was approached with great hope by those brought into contact with large groups of cases in hospitals, but they had changed their opinion; it did not present a large measure of success, except in the very early cases and those of the ascending type. The laboratories were at work and some were offering new etiological factors that certainly opened new avenues of thought. Doctor Roper had reported for the New York Hospital Annex that there were no drugs used, nursing care only being employed (except in one case of serum treatment), and yet in this hospital the mortality was lower than that reported for the city. Specific treatment must wait upon the pathologists and epidemiologists, but meanwhile the management must be worked out in relation to the pathological processes of repair and absorption which took place soon after the infection had occurred. Emphasis should be placed on the counsel of the essayist regarding precision, efficiency, and persistence in treatment.

The public, owing to the courageous stand of Doctor Emerson, the health commissioner, had been awakened to their responsibilities. If this large group of patients were thrown on their own resources, the surgeons would not be performing their obvious duty. The orthopedic institutions of the city would not have room efficiently to care for the large number of cases discharged from the hospitals, and the ordinary dispensary was not fitted nor qualified to do so. This was the time for cooperation with the commissioner and the immediate attention of the association of outdoor clinics, to the end that a uniform standard of equipment might be established so that these children might receive proper treatment and welfare workers follow up these cases so that the parents would be constantly encouraged and the necessarily long course of treatment, as Doctor Lovett had so admirably shown, be persisted in so that the patients, otherwise crippled for life, might be restored to usefulness. If treatment did not seem to produce results and these people were left to themselves, they would drift away.

Dr. Foster Kennedy said that there was nothing that had not been touched on better than he could do it, but he wished to refer to Doctor Lovett's comment regarding the neurologists' lack of enthusiasm for braces compared to their alleged favorable opinion of electricity as a therapeutic measure in poliomyelitis. The speaker did not regard this as an even comparison, for electricity at its worst was at least not more harmful than an incantation, while braces improperly or prematurely used could be destructive.

Neurologists had tried for a long time to discourage the undue use of apparatus during the first two years after the onset of the disease. It was a difference of opinion between them and the orthopedic surgeons, not yet settled. What Doctor Lovett had said would do a great deal to make some medical men less anxious to splint these paralyzed legs. If rigid apparatus was put on a muscle already diminished in innervation, it became still more atrophic and there was more difficulty in helping it to recovery.

It was necessary within six weeks to two months of onset to begin to institute passive movements and massage. This did not mean massage given three times a week for half an hour at a time, but rather for five or ten minutes five or six times a day. If the mother was properly educated, results could be attained in a dispensary which would not be achieved in the homes of the rich, where the patient was treated by a professional masseuse for half an hour or more every other day.

The placing of rigid apparatus on muscles which, though injured, were still capable of development by carefully graduated exercises and massage, both carried out several times a day for short periods, was a very heavy responsibility. The result of doing so was inevitably to increase uselessness in already atrophic muscles. Doctor Lovett had said that operation should not be done until two years from onset. The speaker affirmed also that, generally speaking, no brace should be applied during the same period.

Dr. Abraham Jacobi had seen this disease occasionally during the past sixty years, but not this summer. What had been said about infantile paralysis was not uniform; the cases that had been described, however, seemed much the same as years ago, except that at that time fever was rare. The cases usually had the following history: "A baby was put to bed apparently well and was taken up in the morning paralyzed, with two to four sets of anterior nerves involved. The child was better in five or six days, improvement being rapid; it was less rapid afterward for five or six weeks and this terminated the improvement. He had known of only one exceptional case; the child was treated for two or three years by a peculiarly enthusiastic assistant of his with galvanism, some 600 or 800 applications a year and eventually got nearly well. Treatment should not be undertaken, unless it could be continued over a number of years.

THE AMERICAN ASSOCIATION OF IMMUNOLOGISTS.

Third Annual Meeting, Held at Washington, D. C., May 11 and 12, 1916.

The President, Dr. J. W. Jobling, of Nashville, Tenn., in the Chair.

(*Continued from page 722.*)

A Stable Bacterial Antigen with Special Reference to the Meningococci.—Dr. George Hansen, of Glenolden, Penna., observed that various methods had been recommended for the standardization of antimeningococcus serum, but no method so far devised was considered satisfactory. There had recently been a return to complement fixation, not because it was supposed that complement fixing antibodies had any exact relationship to the therapeutic value of the serum, but because the method was fairly accurate and served to identify the serum with the various types of meningococci with regard to its polyvalency. An antigen which might be distributed to various laboratories and which would remain unchanged under the varying conditions therein would remove one source of variation in results. Further, such an antigen might have value in the case of other bacteria, for instance, the gonococcus.

Cultures for the preparation of dried meningococcus antigen were grown on salt free agar. The growth was collected in distilled water, an equal volume of alcohol was added, and the mixture was centrifugated at high speed. The bacteria were further dehydrated by repeated washing with alcohol and finally with ether. The resulting mass was dried and preserved *in vacuo* over phosphorus pentoxide. For use, weighed amounts of the antigen were ground in a mortar and suspended in physiological saline solution. The usual preliminary titrations and controls were set up to be certain the reactions were specific. The dried antigen had been checked up against its homologous serum and a large number of heterologous serums had been found to yield specific results.

The Wassermann Test.—Dr. Judson Daland, of Philadelphia, was especially interested in Doctor Coca's paper. Clinicians, however, were fully convinced of the importance and great value of the test, and were most optimistic. Speaking broadly, he inclined to the opinion that the Wassermann reaction might be looked upon as having a diagnostic seventy or eighty per cent. value, under ordinary conditions; and under special conditions still greater value. The object to be accomplished by a study of errors of the test was to increase its value; and these errors might be divided into two classes: 1. Laboratory, and 2, clinical errors. The laboratory errors might be due to the many causes with which the members of the society were familiar and occasionally might be due to the methods employed or to gross carelessness. On the other hand, clinical errors might be due to the erroneous belief that syphilis was present or absent, and in such cases when the Wassermann reaction was positive, the error was ascribed to the test. Syphilis might exist and the Wassermann reaction be negative, and they might conclude that the Wassermann reaction had been incorrectly performed and should have yielded a positive result. A common clinical error was failure to recognize the fact that under certain conditions associated with marked disturbances of metabolism, such as uremia, intestinal toxemia, fever, etc., occasionally a serodiagnostic test for syphilis might be strongly positive and syphilis be absent. Obviously such a diagnosis of syphilis solely from the laboratory test, would be a clinical and not a laboratory error. It was of the utmost importance that the society should at once take steps to standardize the serodiagnostic test for syphilis so that the results obtained by the large number of workers might be truly comparable. It was for this reason that he had advocated the original technic described by Wassermann, although during the past four years he had modified it by the use of cholesterinized extract of the bovine heart. From the clinical standpoint, it was of the utmost importance that all factors concerned in the interpretation of the results of the Wassermann reaction should be given due weight before deducing that a positive or negative Wassermann reaction proved the presence or absence of syphilis.

Dr. Oscar Berghausen, of Cincinnati, said that first of all they should be clinicians, able to interpret the laboratory findings in terms of the clinical picture that was presented. A great deal depended upon the antigen. A suitable antigen gave positive reactions in luetic cases and negative reactions in nonluetic cases. The results should be reported as either distinctly positive or negative; doubtful reactions having but little real diagnostic value. A series of antigens, including cholesterinized antigens, should be used in carrying out the reaction. With cholesterinized antigens occasionally false positive reactions were obtained. He had observed such reactions with the blood obtained from patients suffering from advanced malignant disease and uremia Some substance had developed, which appeared in the blood current and was able to find complement in the presence of syphilitic antigens. They should be careful in taking and preserving the blood to be examined. Standing at room temperature, or the delay occasioned by sending the specimen through the mail, might be the cause of false reactions.

Prophylactic and Therapeutic Inoculations in Affections of the Respiratory Tract.—Dr. George W. Ross, Dr. H. K. Detweiler, and Dr. J. C. Maynard, of Toronto, Canada, made particular reference to the "common cold," first concerning its prevalence and the great discomfort, disability and economic loss which it caused. Its etiology was then discussed. Foster's filterable virus and Bacillus rhinitis (Tunnicliffe) and Bacillus influenzæ (Pfeiffer) were referred to as microorganisms which in different epidemics seemed capable of initiating the coryza or other early symptoms. It was thought that the secondary invaders (various streptococci in catarrh, pneumonia, etc.) probably played an important part, and the question was raised as to the likelihood of symbiosis occurring among those organisms, or increasing their parasitism. In connection with the recent epidemic in Toronto, it was shown that Streptococcus pyogenes largely prevailed in cultures from the nose and nasopharynx and sputum.

(*To be continued.*)

Book Reviews

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

A Handbook of Fevers. By J. Campbell McClure, M.D. (Glasgow), Physician to Out-Patients, The French Hospital, London, and Physician to the Margaret Street Hospital for Consumption and Diseases of the Chest, London. Formerly Senior Resident Assistant Physician, Assistant Superintendent, and Resident Medical Officer in Charge of the Smallpox Hospital, Belvidere Fever Hospital, Glasgow. New York: Paul B. Hoeber, 1914. Pp. viii-470. (Price, $3.50.)

This is a handy work in which the discussion of the various fevers is almost entirely confined to practical aspects, the chief aim being manifestly to facilitate their recognition and the application of appropriate treatment. The customary pathological descriptions of textbooks on medicine have been omitted, and but little of epidemiology and bacteriology allowed admission. All that the general practitioner may find it necessary to know is included, however, special sections on the methods of infection, for example, period of infectivity, home prophylaxis, and public health administration being provided. Special attention is paid to the differentiation of the various clinical types in which the diseases taken up may be manifest, as well as to their complications and sequelæ, with the corrective measures indicated. In the sections on treatment the author presents much that is original or at least is based on his personal experience with the various therapeutic means referred to. In typhoid fever he favors giving calomel in small doses steadily for some days or even weeks, finding that it reduces meteorism and abdominal discomfort. In the bowel hemorrhage of the same disease he has found lead, tannic acid, and other astringents of no value, but favors opium, to which strychnine is added in small repeated doses to prevent relaxation of the intestine. Tepid compresses on the abdomen are preferred to cold applications in these cases, as they seem to have some action in restoring the tone of the gut. Kala azar, beriberi, and pellagra are included among the affections considered in this useful book.

Christianity and Sex Problems. By Hugh Northcote, M.A. Second Edition, Revised and Enlarged. Philadelphia: F. A. Davis Company, 1916. Pp. xvi-478. (Price, $3.)

The book begins with a survey of the literature on the subject, which is rapidly attaining a formidable bulk, and then plunges *in medias res*. Sexuality in the child is discussed —incidentally coeducation is denounced—then sexuality in the normal adult, neomalthusianism, sexual promiscuity, with the Bible's statements thereon, prostitution, including rescue work and the "white slave" traffic, venereal disease, marriage, and divorce. Two curious chapters follow, on the sexual in art and on the nature and ethics of impure language. The perversions are next taken up, and the evolution and metaphysical basis of sexual morality. There is an interesting chapter on the virgin martyrs, and the last chapter is concerned with the attitude of the gospel toward sex relations, the Christian ideal of marriage, etc.

The author is a priest of the Church of England and is evidently deeply read in the literature of the subject, scientific as well as poetical, to say nothing of the Scriptural and patristic. He knows his classical poets and the modern English books of Havelock Ellis and a few others. We think that the first thought of his readers will be directed toward what some will consider the broadmindedness of the author, while others will characterize it as disgraceful and unchristian temporizing with the most repellant forms of vice. Indeed it is hard to seize the writer's viewpoint when, for example, he recommends punishment for inversion, yet stipulates that the punishment be a light one.

In France and Italy, we believe, there is no penalty for inverted practices, provided that children are not debauched; the law, in fact, resembles our laws regulating normal intercourse. The attitude in this country toward inversion, however, is so antagonistic that tolerant legislation, Federal or State, is not likely for many years to come. In Europe sexual vagaries have been recognized to the extent of the founding in Germany of a periodical specially devoted to their study. The only remedy seems to lie in suggestion, either during the hypnotic sleep or with the subject conscious and willing. Perhaps Mr. Northcote's book, if widely circulated—and we hope it will be—may centre attention on a really tragic abnormality and modify our views sufficiently to permit of dispassionate discussion with a view to intelligent legislation. One thing seems to be sure—that sexual disorders are not due to criminal or disordered minds, and are quite independent of the will; indeed, they have a singular characteristic, in that their victims are often extraordinarily gifted, usually in music and the arts generally. A common jail, therefore, does not seem to be the proper place for them.

Mr. Northcote notes here and there the great variation, from one individual to another, of the strength of the sexual appetite; this variation seems to be at the bottom of the diverse views of what constitutes sexual temperance, etc. With some young men it is a constant fight with desire, while others seem to be able to shut down on the instinct when they have other important matters to attend to. Middle aged men, too, appear to forget the hot blood of their youth and are overbold in stating that sexual temperance is an easy matter. It is, usually, for men over fifty years of age at all events, unless an attack of senile satyriasis supervenes; but what interpretation do the preachers of continence place upon the red light district of every city, town, and many a village of the country? How have they read the amazing revelations of the various vice committees appointed in our larger towns?

Mr. Northcote speaks with authority to devout and earnest people, and it is to be hoped that his painstaking work will bear fruit in compelling a more unanimous verdict on the phenomena of his vast and newly agitated subject.

Interclinical Notes

The *Medical Review of Reviews* for October, 1916, says some very nice things about the New York Medical Journal, among others that we are "the most interesting of the independent weeklies." We are sufficiently ungrateful to state that we have seldom printed anything more interesting than the following paragraph, which we found on page 761 of our learned contemporary: "Bleeding from the rectum should be considered malignant in origin unless due to some other cause!!!" The exclamation points are our own.

* * *

Mr. Irvin S. Cobb has, in the *Saturday Evening Post* for October 7th, a story, Lover's Leap, which purports to be the diary of a seminary professor. If there is in this broad land any seminary harboring a professor who writes the extraordinary English of the Rev. R. T. Fibble, its name should be published as a warning to possible young women matriculates. Doctor Fibble uses *transpires* for *happens*, apparently does not know that unguents and ointments are the same thing, speaks of a lady as a confrère; he uses the expression, "actual fact," he calls a horse an equine, and a dog a member of the canine kingdom. Professors, as a class, may avoid the lingo of the race track and diamond, but they do not use the inflated jargon of this clerical hero.

* * *

Paul J. Banker is responsible for this paragraph in *Commerce and Finance* for October 4th: Shell shock frequently has been spoken of since the war. The terrific detonation of the heavy artillery has a terrible effect on men's nerves. Men lose their power of speech and hearing and often the use of their limbs. The London *Observer* says that nearly every day the papers contain a paragraph stating that some victim of shell shock has suddenly recovered his speech and the variety of methods is curious. A few are given: 1. Grew excited over a game of cards. 2. Fell downstairs. 3. Had a tooth pulled at the dentist's—without anesthetic. 4. Choked through inhaling cigarette smoke. 5. Underwent a flashlight photograph. 6. Put the wrong end of a lighted cigarette in his mouth. The *Observer* observes that "the card cure on the whole seems the least painful."

Meetings of Local Medical Societies

Monday, *October 16th.*—New York Academy of Medicine (Section in Ophthalmology); Yorkville Medical Society; Medical Association of the Greater City of New York; Medical Society of the County of Erie; Elmira Clinical Society; Psychiatric Society of Ward's Island.

Tuesday, *October 17th.*—New York Academy of Medicine (Section in Medicine); Tompkins County Medical Society; Medical Society of the County of Monroe; Buffalo Academy of Medicine (Section in Obstetrics); Tri-Professional Medical Society of New York; Medical Society of the County of Kings; Binghamton Academy of Medicine; Syracuse Academy of Medicine; Ogdensburg Medical Association; Oswego Academy of Medicine; Federation of Medical Economic Leagues.

Wednesday, *October 18th.*—New York Academy of Medicine (Section in Genitourinary Diseases); Alumni Association of City Hospital, New York; Schenectady Academy of Medicine; Women's Medical Association of New York City (New York Academy of Medicine); Medicolegal Society, New York; Buffalo Medical Club; Northwestern Medical and Surgical Society of New York; Bronx County Medical Society.

Thursday, *October 19th.*—New York Academy of Medicine (stated meeting); Auburn City Medical Society; Geneva Medical Society; German Medical Society, Brooklyn (annual); Æsculapian Club of Buffalo; New York Celtic Society.

Friday, *October 20th.*—New York Academy of Medicine (Section in Orthopedic Surgery); Mount Vernon Medical Society; University of Virginia Medical Society; Clinical Society of the New York Post-Graduate Medical School and Hospital; New York Microscopical Society.

Official News

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers of the United States Public Health Service for the seven days ending October 4, 1916:

Bahrenburg, L. P. H., Surgeon. Directed to attend the meeting of the South Texas District Medical Association at Orange, Tex., October 5 and 6, 1916.

Bailey, Charles A., Acting Assistant Surgeon. Granted one year's leave of absence without pay from October 6, 1916.

Carter, H. R., Assistant Surgeon General. Granted two months' leave of absence without pay from October 20, 1916.

De Saussure, R. L., Assistant Surgeon. Granted three weeks' leave of absence from October 20, 1916.

Draper, W. F., Passed Assistant Surgeon. Directed to deliver an address on public health at a meeting of the Civic League at Potter's Hill, Va., October 10, 1916.

Frost, W. H., Passed Assistant Surgeon. Granted three days' leave of absence, September 24 to 26, 1916, and one day, September 30, 1916.

Glennan, Kenneth R., Field Investigator. Directed to proceed to Toledo, Ill., for duty in studies of rural sanitation.

Glover, M. W., Surgeon. Department letter of August 25, 1916, amended to grant sixteen days' leave of absence on account of sickness from August 20, 1916.

Grimm, R. M., Passed Assistant Surgeon. Granted fifteen days' leave of absence from October 16, 1916.

Heterick, R. H., Passed Assistant Surgeon. Directed to report at the Bureau for conference relative to anticipated trip to Tampico, Mexico.

McKeon, F. H., Surgeon. Directed to assume charge of Fort Stanton, N. M. Sanatorium.

Miller, K. E., Assistant Surgeon. Directed to proceed to Nashville, Tenn., for conference with State Boards of Health on October 2, 1916.

Ramus, Carl, Surgeon. Relieved from duty at Ellis Island, N. Y., and ordered to proceed to Naples, Italy.

Rucker, W. C., Assistant Surgeon General. Directed to proceed to Baltimore, Philadelphia, and New York relative to discontinuance of measures for the prevention of interstate spread of poliomyelitis; granted seven days' leave of absence on account of sickness from September 21, 1916.

Saunders, Samuel, Field Investigator. Directed to proceed to Toledo, Ill., for duty in studies of rural sanitation.

Schereschewsky, J. W., Surgeon. Directed to attend the meeting of the National Safety Council at Detroit, Mich., October 17-20, 1916.

Sharp, W. J., Field Investigator. Directed to proceed to Tuscaloosa, Ala., for duty in studies of rural sanitation.

Smith, F. C., Surgeon. Relieved from duty at Fort Stanton, N. M., and directed to proceed to Cape Charles Quarantine Station.

Storrs, H. R., Acting Assistant Surgeon. Directed to proceed to Seattle, Wash., for instruction in examination of cholera carriers.

Warren, B. S., Surgeon. Directed to proceed to Boston, Mass., for conference with the State Department of Health.

Births, Marriages, and Deaths

Married.

Hollings-Walker.—In Norwood, Mass., on Monday, October 2nd, Dr. Byam Hollings, of Waverly, and Miss Alice Walker.

Moser-Kierstead.—In East Hartford, Conn., on Wednesday, September 27th, Dr. Oran A. Moser, of Rocky Hill, and Miss Lottie E. Kierstead.

Northridge-Taylor.—In Biddeford, Me., on Wednesday, October 4th, Dr. Robert J. Northridge, of Worcester, Mass., and Miss Elizabeth E. Taylor.

Wood-Heidbrink.—In St. Louis, Mo., on Friday, September 22nd, Dr. William J. Wood, Jr., and Miss Ida Heidbrink.

Died.

Aldrich.—In Albany, N. Y., on Thursday, September 28th, Dr. William D. Aldrich, aged thirty-three years.

Barry.—In Hot Springs, Ark., on Tuesday, September 26th, Dr. William H. Barry, aged eighty years.

Daniel.—In Claxton, Ga., on Saturday, September 30th, Dr. A. B. Daniel, aged eighty-two years.

Dominick.—At sea, on Monday, October 2nd, Dr. George Dominick, of New York, aged thirty-nine years.

Ellsberry.—In Bethel, Ohio, on Saturday, September 9th, Dr. William S. Ellsberry, aged sixty-four years.

Everett.—In Remsen, N. Y., on Monday, September 25th, Dr. Mary H. Everett, aged eighty-six years.

Green.—In Mexico, N. Y., on Wednesday, October 4th, Dr. Tobias J. Green, aged ninety-eight years.

Hornblower.—In Jersey City, N. J., on Thursday, October 5th, Dr. Josiah Hornblower, aged eighty years.

Howe.—In Bristol, R. I., on Sunday, October 1st, Dr. Herbert Marshall Howe, aged seventy-two years.

Keep.—In Brooklyn, N. Y., on Saturday, September 30th, Dr. J. Lester Keep, aged seventy-eight years.

Lloyd.—In Baltimore, Md., on Thursday, September 19th, Dr. Louis L. Lloyd.

Magie.—In Princeton, N. J., on Tuesday, October 3rd, Dr. David Magie, aged seventy-five years.

Mease.—In Goldsboro, N. C., on Sunday, September 24th, Dr. John H. Mease, aged forty-four years.

Moore.—In Philadelphia, Pa., on Tuesday, September 26th, Dr. William D. Moore, aged forty-nine years.

Pierce.—In Worcester, Mass., on Monday, October 2nd, Dr. George J. Pierce, aged seventy-six years.

Severance.—In Tacoma, Wash., on Tuesday, September 26th, Dr. A. Edward Severance, aged sixty-two years.

Solandt.—In Hayden, Col., on Tuesday, September 26th, Dr. John V. Solandt, aged forty-seven years.

Wolsey.—In Buffalo, N. Y., on Wednesday, September 27th, Dr. Cardinal T. Wolsey, aged sixty-seven years.

CONSIDERATIONS IN THE MEDICAL TREATMENT OF GOITRE.*

BY J. M. ANDERS, M. D., LL. D.,
Philadelphia,

Professor of Medicine, Medico-Chirurgical College.

The medical treatment of goitre must have special reference primarily to the particular clinical variety. For example, if the given case in hand is of the nontoxic form, then iodine and thyroid extract are indicated, as a rule, but if of the toxic type, or exophthalmic goitre, then these medicaments would be for the most part pernicious in their influence. Confessedly difficult, it is, nevertheless, all important from the standpoint of treatment to make an accurate diagnosis, including the special variety. The exigencies of time and space, however, will prohibit more than a brief reference to this aspect of the subject.

In the simple hypothyroid type (Sajous) the following group of features should be present: Slight enlargement of the thyroid gland (soft but not tender), more marked on the right side; hypothermia of slight degree; slow pulse ranging from 64 to 40 a minute; the hands and feet cold, excessive sweating, especially on exertion, and bodily fatigue on slight muscular exercise.

In the toxic (exophthalmic) goitre, the enlarged gland is tender to palpation, while tachycardia, tremor, exophthalmos, and other features are present as a rule, and serve to differentiate this, the commoner variety, from the type under consideration. After eliminating Graves's disease, we can approach the medicinal treatment of the hypothyroid type with a feeling of confidence, provided that the case in question has not been allowed to pass beyond the acute and subacute stages into the chronic form where surgery alone suffices to accomplish a cure of the existing deformities.

Again, some of these cases, if untreated, in the course of time cross the threshold of the hypothyroid into the hyperthyroid type. On the other hand, if recognized early this form yields promptly to appropriate treatment.

Sodium iodide often proves efficient, in gradually ascending doses, beginning with five grains three times a day, although the maximum dose should not exceed ten grains. If symptoms of iodism, which should be carefully watched for, develop, the use of the iodides should be temporarily interrupted, and later resumed in smaller doses. In my experience, the tincture of iodine, in gradually increasing doses, beginning with one drop, three times daily, is to be preferred in cases in which gastrointestinal fermentation is an accompaniment.

In this class of cases, thyroid function is deficient as a rule, hence the extract of this gland often exhibits a specific action, but it should be omitted from consideration when iodine proves curative. The daily quantity when used should not exceed five grains, while the beginning dose should be small, e. g., one grain three times daily, and the effects carefully noted. If the pulse rate is not noticeably accelerated, a slow and gradual increase in the dose may be made (one quarter grain three times a day at the end of each week) until the maximum is reached.

Sajous (1) suggests that the total daily dose of the remedy should be administered at night, believing that its use on retiring "protects the heart through the avoidance of exertion while the drug is being assimilated"—a suggestion worthy of more general adoption, especially in cases in which this method of administration does not cause an increase of the pulse beyond ten or twelve beats a minute.

It has always seemed to me to be the part of wisdom to discontinue the iodine in cases in which the thyroid extract is exhibited, on account of failure of the former remedy to bring about a cure. If, however, the desiccated thyroid extract, like the iodine, fails when employed alone, then these remedies should be given simultaneously, their action being almost identical, notwithstanding.

Should untoward effects result from the thyroid medication, they may be successfully combated by two to three minim doses, thrice daily after food, of Fowler's solution. The fact that we are unable to determine clinically, in all cases at least, whether or not hyperthyroidism has already set in, should make us exercise caution and reserve in the administration of so potent a remedy for harm as thyroid extract. Disappearance of goitre should be the signal for the discontinuance of the remedy, but a recurrence, however slight, should lead promptly to its readministration.

It is customary to prescribe an ointment of biniodide of mercury. This with massage over the gland favors absorption of the hyperplasia. Should

*Read at the annual meeting of the American Therapeutic Society, Detroit, June 9, 1916.

Röntgen exposures be resorted to in these cases of hypothyroidism? In my view the measures suggested above should be given a thorough, painstaking trial before using the x ray treatment. I have, however, observed good results from this method in some half dozen cases. It is stated by certain writers that it may produce "intense hyperemia and muscular adhesions, which increase the danger when an operation becomes necessary."

Finally, it may be repeated that the treatment of this type of goitre is entirely satisfactory, provided that the condition is recognized early enough, and iodine and the other agents recommended above are judiciously and promptly employed.

MEDICAL TREATMENT OF GRAVES'S DISEASE.

In the first place, it should be stated that thyroid extract and iodine are contraindicated in the therapeutics of this form of goitre, if we except cases in which myxedematous changes occur as the sequel of secondary atrophy of the thyroid gland. The signs and symptoms of the concurrence of Graves's disease and myxedema are mental dullness, dryness of the skin, falling of the hair, scleroderma, and, more important, supraclavicular swellings and a non-pitting edema. In this class of cases thyroid feeding from time to time is most useful in removing the features just enumerated.

One of the principal factors in the treatment of Graves's disease consists in the removal of recognizable causes. Certain writers describe a "secondary" or symptomatic variety, superinduced by special sources of irritation. It is undeniably true that the removal of these foci may, in rare instances, result in decided benefit, but I know of no cures that have been effected in this manner. Putnam (1), however, correctly observes that "when the nervous system has been under the tax of bearing several loads at once, the removal of any one of them may suffice to communicate a new "set" to the nerve functions or to provide the amount of relief needed to make recovery possible." It follows that an attempt should be made to remove intensifying sources of peripheral irritation whenever found to exist, with the reasonable hope of rendering medical and hygienic measures effective.

Among other prominent causative factors are emotional excitement, shocks, tuberculosis, rheumatism, syphilis, and intoxication from the intestinal canal.

When Graves's disease supervenes as a sequel of acute rheumatism, the use of sodium salicylate often yields excellent results. The writer has seen at least one striking and apparently complete cure from the exhibition of the salicylates. Their use should be interrupted for a few days at intervals of about one month. In cases in which syphilis is associated with Graves's disease, the employment of salvarsan is to be advised and encouraged. In a case reported by Ziegel (3), favorable results were obtained.

In four fully developed cases recorded by Epstein, as the result of large rectal injections of oil, with the purpose of removing all impacted fecal masses, an absolute cure was established. He holds that coprostasis with absorption of intestinal toxins is a very common symptom of the disease, and even in cases in which diarrhea is present there may be pronounced fecal impaction. W. H. Thompson likewise emphasizes the possible influence of autointoxication from the intestines as a causal factor, and excludes all meats from the dietary in order to prevent its development.

S. Solis-Cohen (4) states "whether or not the disorder is originated by the absorption of toxic products from the intestine, it is certainly aggravated thereby." In my belief, a careful regulation of the diet, thorough evacuation of the intestine by means of colonic irrigation with either a hot saline solution, as advised by Cohen, or large oil injections as recommended by Epstein, once or twice weekly, to obviate toxic absorption, cannot be too strongly emphasized. I have found heavy mineral oil administered internally of much service in unloading the bowel during the intervals between the irrigations.

Intestinal antiseptics are of distinct value in selected cases of exophthalmic goitre, the most effective, in my experience, having been betanaphthol, salol, and guaiacol carbonate.

Cases in which a clinical factor, other than shock, physical or emotional, is operative, do not lend themselves to satisfactory medical treatment. In my belief, this view is tenable in no limited sense, judged by an extensive experience. True it is that many of the distressing and alarming symptoms can be relieved by various vaunted remedies, and in exceptionable cases, a cure may follow; but rarely indeed are the results so favorable as those achieved by timely surgical intervention. Clearly, since the knife offers so much more than our therapeutic armamentarium in these cases, it is the plain duty of the internist and general practitioner to request surgical aid without too much delay. If operation is refused by the patient—a not infrequent occurrence—or a contraindication exists (rarely), then medical treatment should be undertaken.

At the outset it is to be recollected that certain hygienic measures are vastly more important to the patient than any known drugs or organotherapy. These patients are often greatly injured by being advised to travel or to take active exercise. What they need in view of the presence of the circulatory disturbances, increased metabolism, and myasthenia, is rest of both body and mind. At the beginning of a course of treatment, massage and passive exercise should be substituted for muscular activity. Later, with improvement in the patient's strength, gradually increased exercise, carefully prescribed, may be advised, but should not be carried to the point of fatigue.

Hydrotherapy has been found to be useful. In general, however, a daily tepid bath to insure cleanliness is sufficient. Baths that tend to induce exhaustion are contraindicated. The environment should be cheerful, but free from mental excitement on the one hand, and all depressing influences on the other hand. The value of fresh air, judiciously taken, is undoubted. In addition to the usual methods of taking the air, the patient should be encouraged to recline out of doors, well protected against cold, sudden changes of temperature, and strong winds. The foregoing measures—rest, followed by suitable exercise, fresh air, a proper environment,

and bathing—are more useful than drugs in controlling tachycardia, neurasthenia, and insomnia.

It is sometimes necessary, however, to supplement them by other means. For example, the tachycardia and palpitation may require the use of an ice bag over the precordia, and a weak, rapid heart the administration of cardiac stimulants. As regards digitalis, it may be said that it often fails to control the tachycardia of this disease, and when employed it should be discontinued when found to be without favorable effect. Strychnine in small doses is effectual in combating cardiac weakness.

Of the numerous available remedies which have been advocated, two are worthy of elaborate mention. These are quinine hydrobromide and antithyroidin Möbius, the latter being prepared from the serum of thyroidectomized sheep and preserved by the addition of 0.5 per cent. carbolic acid. This product is available in bottles containing two and a half drams (ten c. c.) and may be administered in doses ranging from ten to sixty minims, two or three times daily. It has no cumulative action.

It is customary to continue the use of antithyroidin until the contents of one bottle are taken, and then to omit it for a few days, when it is to be resumed. Unfortunately, we are still ignorant, as Dock has pointed out, of the amount of this remedy requisite for the best results. Elsner and Wiseman (5) state that antithyroidin confers benefit "by relieving the annoying and alarming symptoms of exophthalmic goitre in typical and atypical cases." In their experience the greatest improvement is found in the relief of the tachycardia, precordial distress, and tremor. This improvement was hastened by rest in bed and close attention to diet, and in serious cases it was necessary to continue the treatment during many months.

Personal experience confirms that of Elsner and Wiseman just cited. Antithyroidin causes the enlarged thyroid to lessen in size, but not beyond the normal dimensions. The relief afforded to the distressing nervous phenomena of the disease, by antithyroidin and its apparent harmlessness, combine to stamp this as a sovereign remedy in exophthalmic goitre. As in the case of the use of thyroid extract in myxedema, so it is found wise to administer antithyroidin after the active symptoms have subsided, during periods varying from four to eight weeks, at intervals of two to three months.

The second remedy worthy of careful consideration in connection with the therapy of Graves's disease is the neutral hydrobromide of quinine, first proposed by Forcheimer. My custom has been to prescribe it in five grain capsules three times a day after food, later increased to four doses of the same strength, daily, if well borne. The remedy is to be continued until the subjective symptoms, the tachycardia, and tremor have disappeared, after which it is to be diminished until a single dose is taken daily. Should active symptoms arise during this tentative withdrawal of the drug, it must be resumed in full doses at once. The hydrobromide of quinine antagonizes hyperthyroidism, probably owing to its vasoconstricting effect, but it does so in a slow and gradual manner, hence patients should be told that they must be prepared to use it continuously for a period of months.

THE EARLY DIAGNOSIS OF TUBERCULOSIS.

BY EDWARD O. OTIS, M. D.,
Boston.

> "The physician ought in the first place to endeavor to ascertain the nature and state of the disease by the common symptoms alone."
>
> JOHN FORBES.

In the experience of the writer a timely recognition of clinical tuberculosis is now more frequently made by the general practitioner than was the case in the past; indeed, the pendulum almost seems to have swung the other way and the specialist is not infrequently consulted by a frightened victim of undue zeal on the part of the doctor, who has made the dreaded diagnosis of tuberculosis upon slight or questionable physical signs or upon the x ray picture, regardless of the fact that no constitutional symptoms exist; he has made the mistake of calling a tuberculous infection an active tuberculosis. This distinction must always be borne in mind. Clinical tuberculosis means active disease indicated by its characteristic *symptoms*, such as cough, increased temperature, rapid pulse, loss of weight and strength, slight dyspnea on exertion, etc. There may even be no definite physical signs, but the toxemic symptoms plainly reveal the disease. On the other hand, nonclinical tuberculosis may show definite physical changes in the lungs, but there are no symptoms, and no deviation from normal well being—the subject is in no way ill and requires no treatment.

There are other cases, however, in which a definite diagnosis cannot be made at a first examination or at a second one. We can only keep the patient under observation and carefully watch developments. The symptoms are too indefinite and not corroborative one of another; the physical signs are indeterminate. Our suspicion is aroused, but only time can dispel or confirm it.

A belated diagnosis, or the failure to make one when the evidence is adequate, is still, however, only too common, and this may lead to disastrous results, as we all know too well. A striking and sad example of the failure recently came under the observation of the writer. A young woman, married but three weeks, was found to be suffering from well marked and well advanced tuberculosis with very active symptoms and very plain physical signs. She had been told by two physicians whom she consulted that she had only some "throat trouble" and so misled she married, only to awake to the distressing fact at the end of her honeymoon that she was a sufferer from the dreaded disease which had existed long before her marriage. How much needless suffering and disappointment did

this mistake entail upon her and her unsuspecting husband! She had lost her best chance of recovery and the new home was broken up.

The fault in not making an early diagnosis lies largely, it seems to the writer, in the neglect of a careful study of the symptoms, which everyone can make with patience and time, and in placing dependence upon too slight and inadequate physical signs, of which even the specialist cannot always be sure. If the physicians in the case cited had only studied the symptoms, the diagnosis would have been evident.

It requires much time and careful investigation under quiet conditions to make an early diagnosis of tuberculosis. We cannot make it in a hurry. The history of the patient has to be carefully investigated, and, in the experience of the writer, the personal history is of more importance than the family history: What has been the patient's previous mode of life? His past illnesses? His occupation? His habits? His environment at home and at work? His excesses or deprivations? Anything and everything relating to the past life of the patient may give valuable clues; if, for example, the occupation is a dusty one, this is a significant fact, for we know that the incidence of tuberculosis is materially greater in dusty occupations, especially where the dust is metallic or mineral. Or is it an occupation which requires excessive physical or mental demands and close indoor confinement? Again, the question of exposure to infection, as in a family where one member is suffering from the disease, or long and intimate association with a tuberculous person in office or workshop is an important fact to ascertain. Past illnesses, such as pleurisy, influenza, typhoid fever, recurring bronchitis, and syphilis, suggest a lowered resistance or a tuberculous infection awakened into activity by one or another of these diseases.

In obtaining the history of the present illness we may either ask the patient when and how he first began to feel ill and what symptom he first noticed, or perhaps better, when he last felt perfectly well. As to the first symptoms observed, the patient will generally give one or more of the following: 1. A slight but persistent cough, or he may call it a cold which "hangs on"; 2, loss of strength or nervous energy—he does not feel quite up to his former physical condition, he gets tired more easily; 3, loss of weight, which may be but slight; 4, hemoptysis, which always brings the patient to the physician and which is almost a pathognomic symptom of pulmonary tuberculosis; 5, slight dyspnea on exertion; 6, pain in the chest or referred to the shoulder blade; 7, chilliness followed by flushing or feeling of undue warmth, indicative of fever; 8, loss of appetite or digestive disturbances; 9, hoarseness. Of all these symptoms perhaps the most common one is loss of energy or "ambition." We should be very careful to inquire into the matter of cough and expectoration, for these symptoms (cough and expectoration) may be so slight that the patient may at first deny that they exist. Although specific questions must be asked, yet it is often illuminating to allow the patient to tell his story in his own way.

We cannot be too painstaking in eliciting and studying the symptoms when making a diagnosis of pulmonary tuberculosis, for upon them we shall have to depend largely, if not entirely, for definite symptoms are frequently present before physical signs appear or at most the physical signs are indefinite and doubtful. On the other hand, it may be repeated that physical signs without symptoms mean only that there is a latent tuberculous infection and not an active process. The mistake is not infrequently made of acting upon physical signs without the accompanying symptoms, and consigning the individual to active treatment in the sanatorium or elsewhere to the disruption of his economic and social life. Thus his whole career and life may be ruined and marriage and self support prevented.

The temperature and pulse are of great significance, but in order to obtain an accurate gauge of the former, the temperature, it should be carefully taken for a week, three or four times a day, at eight, twelve, four, and six or seven o'clock. The patient may generally be taught to take it himself, or some one of his friends may do it. A constant although slight rise of temperature (99.5° F., or over) usually occurring in the afternoon, or a subnormal temperature accompanied by a persistently rapid pulse is very significant. When these two conditions exist, viz., a slight and constant rise of temperature in the afternoon and a rapid pulse, and at the same time they are accompanied with a little loss of weight and strength and some nervous instability, the case for the existence of pulmonary tuberculosis is a strong one. We must remember that a case of tuberculosis may simulate neurasthenia in its symptoms, and hence in every case of the latter condition a careful examination of the lungs should be made.

In the physical examination, which it is hardly necessary to say, should be made with the patient stripped to the waist; we first have to *look* at the chest and much information can often be obtained by the glance of the trained eye. We can see if there is, 1, any greater depression on one side than on the other, above and below the clavicle; or 2, whether there is less movement at one apex than the other, both of which are very suggestive signs of a tuberculous process. When we come to percussion and auscultation, the whole chest should, of course, be examined front, back, axillary region and base. It is true that evidence of a tuberculous infiltration is generally found at the apices, still there are exceptions, consequently the whole chest should be examined minutely.

In percussing, we should proceed from below upward, because at the lower part of the chest we generally obtain the normal resonance which can be taken as the standard for the individual. It must be remembered that at the right apex there is a physiological difference in the percussion sound from that at the left apex; at the right apex the sound is not so resonant and is of a higher pitch and, moreover, the respiratory sounds are harsher and the voice sounds decidedly more intense. All this is normal for the right apex. If we found the same condition at the left apex it would indicate some slight degree of consolidation. Generally in early cases, percussion will not give very definite information, for a slight diminution

of resonance is difficult of determination. When unmistakable dullness is present, the case has passed beyond the initial stage. Sometimes when there is a marked degree of infiltration in both lungs, the resonance, although greatly impaired, may be so nearly the same on both sides that we may fail to recognize that dullness exists. This is particularly the case when there are no adventitious sounds.

It is principally upon auscultation that we must depend for physical signs in early diagnosis, and often such auscultatory signs will be so indefinite and slight that their interpretation is difficult if not impossible. Both in auscultation and percussion we can discriminate better between slight differences in pitch and sound if we have a musical ear and are ourselves musical. The elder Flint, that great master of auscultation and percussion, played upon the violin. Laennec, the discoverer of mediate auscultation, played upon the flute, and Auenbrugger, the discoverer of percussion, was passionately devoted to music.

In auscultation we should study first the respiration, then the voice sounds, whispered and spoken, and, last, seek for adventitious sounds, namely, rales. The ability to distinguish abnormal respiratory sounds must depend upon a clear recognition of the normal respiratory murmur. "You cannot study too frequently or too minutely," said the elder Bowditch, nearly seventy-five years ago, "the respiratory murmur and the voice in healthy persons."

In early tuberculosis, one of the most significant modifications of the respiratory murmur is what Turban calls "rough" breathing, in contradistinction to the smooth vesicular respiration. We may also have a distinct diminution of the respiratory murmur upon the affected side. The expiratory murmur may also be distinctly prolonged and may be more or less bronchial in character—the bronchovesicular murmur of Flint. "This sign," he says, "represents the different degrees of consolidation of the lung between an amount so slight as to occasion only the smallest appreciable modification of the respiratory sound, and an amount so great as to approximate closely to the degree giving rise to bronchial respiration."

"Cogwheel" or intermittent respiration, in my experience, is of little value, as it is frequently heard when there are no other abnormal signs.

After all is said, slight modifications of the respiratory murmur are often difficult of detection and of limited value in diagnosis. "Distinctions in the (respiratory) murmur," says Gee, "which correspond with no definite physical condition of lung, make a show of profound and accurate knowledge, but really obscure it. They are *idola theatri*."

The voice sounds, spoken or whispered, if increased, indicate, of course, some beginning consolidation over the area in which they are heard, but it must be remembered that usually the voice sounds are much louder at the right apex than at the left, and when they are of equal intensity at both apices, it is an indication that there is some consolidation at the left apex.

Rales are, by far, the most significant of all the auscultatory signs, for they are definitely abnormal, and when persistent and localized, even if but few and feeble, they have far greater weight in making an early diagnosis than any deviation in the respiratory murmur. In seeking for rales we must never forget to have the patient cough, and then take a full breath immediately thereafter, for thus rales may be detected which would not otherwise be discovered. Turban mentions the incident of a patient who had consulted many physicians and who estimated their diagnostic ability by noting whether they asked him to cough during the examination. We must agree with Hector McKenzie that "the earliest physical sign which is *really* characteristic is the presence of rales." Although rales may not be regarded as the earliest physical sign of tuberculosis, the majority of physicians will make their diagnosis depend largely, so far as the physical signs are concerned, upon the detection of rales. "The detection of rales by the auscultation of the inspiration following cough," says Lawrason Brown, "is the most important procedure in the detection of physical signs of early pulmonary tuberculosis." Unilateral rales, with or without other physical signs at the base of the lung, have not infrequently led to the diagnosis of tuberculosis and the sending of the patient to the sanatorium. If there is no discoverable affection at the apex of the same lung, the basic condition must be considered to be due to causes other than tuberculosis.

After the most careful physical examination we shall often be unable to detect definite evidence of disease if we base our diagnosis upon physical signs alone, for as Knight truly observes, "variations in the respiratory murmur and slight modifications of the percussion note are not enough for positive diagnosis, and a patient should not be condemned to radical treatment upon such insufficient evidence." It is chiefly upon the symptoms, be it repeated, that we must depend for early diagnosis, unless we are so fortunate as to discover tubercle bacilli in the sputum, or detect persistent localized rales, or hemoptysis has occurred not referable to any other source.

In every suspected case, an examination of the sputum should be made and several times repeated if tubercle bacilli are not found upon the first examination. This examination is now so simple, easy, and rapid that no practitioner is excusable for not being able to do it. Although we can often be morally certain that tuberculosis exists from the symptoms and physical signs, yet absolute certainty can be determined only by finding the specific organism in the sputum, for it is possible that the symptoms which we regard as those of tuberculosis may be caused by other conditions. "Active disease confined to an apex," says Glover, "with a repeatedly negative sputum is not common." If from all the evidence obtained we are unable to make a positive diagnosis or a probable one sufficiently strong to warrant active treatment, we must keep our patient under observation and make repeated examinations at short intervals.

There are other helps to a diagnosis which, under favorable circumstances, may be available, namely, the x ray and the tuberculin test. Unless the former—the x ray—is done by an expert technician, and we are quite familiar with interpreting

x ray plates, it is not of much aid, and, moreover, a diagnosis of active tuberculosis should never be made from the x ray picture alone as is sometimes done.

The tuberculin test can be employed in exceptional cases and its application is easy. Here again, however, it tells us nothing as to the activity or latency of the disease. "No modification of the tuberculin test as yet devised," says Brown, "differentiates clearly clinical tuberculosis that demands vigorous treatment from nonclinical tuberculosis that requires only a God-fearing life."

In conclusion, the diagnosis of early clinical tuberculosis depends upon the careful and painstaking assembling, correlation, and study of the symptoms, together with the evidence of the temperature and pulse and such definite physical signs as can be clearly discerned. The main reliance must be upon the symptoms, the pulse, and the temperature. If the physician spent the major part of his time and efforts in studying the symptoms and less upon the attempt to determine uncertain physical signs, I am convinced that but few cases would slip through his hands unrecognized.

REMOVAL OF THE THIRD LOBE OF A CYSTIC GOITRE.*

From a Woman with Exophthalmos,

By A. Ernest Gallant, M. D.,
New York.

The points of interest which led to a report of this case were:

1. The mother and five sisters had goitre and were said to have been cured by medicine.

2. The successive enlargement of the right and left lobes after removal of the middle lobe, with intervals of fourteen and four years respectively.

3. The aphonia following the second operation,

Fig. 1.—The third (left) lobe at the third operation, October 12, 1907.

Fig. 2.—Side view of third lobe shown in Fig. 1.

and restoration of the voice after the third operation.

4. The very disagreeable effects when thyroid gland or potassium iodide was administered.

5. The almost uninterrupted discharge from the sinus, and the serious discomfort and "queer feelings" whenever the sinus closed temporarily and the secretion could not escape.

6. The marked diminution of the exophthalmos.

7. The return of a considerable growth of hair in a woman of her age.

Case (65). On October 2, 1907, Mrs. A. F., German, aged forty-eight years, secundipara, came to the Westside German Dispensary on account of reappearance of a "goitre," the third of its kind. She was thoroughly familiar with the phenomena, as her mother and five sisters had had the same condition, "and were cured by medicine." The growth was first noticed when she was fourteen years old, and when it had reached about the size of the present tumor, it was removed by Dr. F. Kemmerer in 1892. Later, the "right" lobe enlarged and was removed at Roosevelt Hospital in 1903, and was followed by complete loss of voice, which became only a whisper. Since then the exophthalmos had somewhat diminished, but was still quite in evidence (Fig. 1). On the *left* of the median line in the neck was a semielastic tumor, with a surface diameter of three inches and an elevation of nearly two inches (Figs. 1, 2). The patient's general condition was underweight; no anemia; pulse somewhat irregular and intermitting occasionally. She was very nervous and able to do but little work, which her husband's illness had compelled her to undertake.

Fig. 3.—Open sinus, November 22, 1908: S, sinus.

The third operation was done, October 12, 1907, at the Baptist Deaconess' Home. Morphine, one quarter grain, was dissolved on the tongue a short time before etherization. For convenience in operating, the patient was placed in a semireclining posture. A vertical median incision alongside the old cicatrix was carried from the hyoid down to the suprasternal notch, and extended to the left, at a right angle for one and one half inch. The tumor was extremely vascular, and in cutting through the capsule some large veins were severed and bled profusely. The growth extended over an area five by six inches, well under the left sternomastoid nearly to the hyoid above, and dipped down below the sternal notch, behind the sternum, for some two inches. During the blunt enucleation the left superior vein was torn, the superior thyroid artery ligated, and several cysts were ruptured. Catgut sutures were carried completely across the base and, when tied, obliterated the cavity. The sheath and fascia were united with a continuous suture, and the skin approximated with silkworm gut. A rolled gauze wick saturated with adrenaline solution was inserted at the lower angle and another into the cavity behind the sternum.

Fig. 4.—Sinus still open, March 3, 1915.

The patient stood the operation well and when put in bed the pulse was 120, regular, and the face a good color. Later the pulse intermitted frequently, but was of fair quality when stimulated by a saline whiskey enema. Shortly after the operation the patient's hair fell out.

*Read as a part of the Symposium on Goitre, before the American Therapeutic Society, at the seventeenth annual meeting, Detroit, Mich., June 9 and 10, 1916.

January 22, 1908. Ever since the operation there had been a constant free discharge of a gummy secretion, which did not diminish, and the sinus manifested no evidence of closing. The sinus was curetted to a depth of one and a half inch, and packed with adrenaline gauze, after the application of pure carbolic acid to the bottom of the canal.

November 22, 1908. During the past ten months the discharge did not cease (Fig. 3). The protruding granulations were cut away and red iodide of bismuth powder was applied. A week later, the sinus closed over.

March 3, 1915. From time to time during the past seven years the sinus has reopened and the discharge recurred for a while; but the patient has always experienced such distressing, nervous feelings when there was no discharge as to make her encourage it to flow.

When last seen, March 3, 1915 (Fig. 4), the exophthalmos had disappeared, her hair had grown in to about its original, scanty quantity, the voice had gradually returned, though it was of a lower pitch. Owing to her stiffened fingers, she has been able to do but little work, and suffered from lack of nourishing food. As a last resort she applied to a charitable organization for help. They promised to look after her welfare, furnish much needed glasses, and to have her badly decayed teeth replaced by a set of "store teeth."

If the patient can be found, it is my purpose to institute the feeding of " thyroid residue" (John Rogers, *New York State Journal of Medicine*, May, 1916, pp. 232-237) and report the result.

616 Madison Avenue.

FOCAL POINTS OF INFECTION.*

Suggestions for Locating Them,

By Noble P. Barnes, M. D.,
Washington, D. C.

To the student of rational therapeutics there is no problem of greater interest than focal infections and the many clinical manifestations that are brought daily to his attention. The result of the painstaking and systematic research in rounding up and exterminating these Villa bands is even now of sufficient proportions to mark a new era in scientific medicine and surgery.

Such foci are now regarded as real and important factors in the diagnosis and treatment of many disorders, some of which have been classed as incurable. Carious teeth, dental alveoli, tonsils and adenoids, gallbladder, prostate, and appendix, sinuses, mastoids, and many other nooks and corners, favorite breeding places and portals, have been found guilty of harboring enemies to health and happiness.

The apprehension of these hiding places brings into employment every diagnostic method known to science. The application of recently gained knowledge respecting the character and characteristics of microorganisms and the practical adjustment to newer conditions of some of our old observations, furnish us with additional means not only of recognizing these offenders but of locating their favorite haunts.

Different animals have a preference for different lairs. Different families of the human race find health and comfort under entirely different environments. A person away from his native country may fail in health, to be restored to normal only by repatriation. Likewise we now have known facts regarding the habits of certain types of microorganisms that give important evidence respecting their tissue affinity. The following are recognized facts respecting the tissue selection or predilection and habits of some of the well known microorganisms:

Those of typhoid, dysentery, and cholera select the digestive tract.

The gonococcus has a fondness for the genital mucosa and the conjunctiva.

The Klebs-Löffler bacillus shows a preference for the tonsils.

The meningococcus invades the upper meninges.

The pneumococcus pervades the respiratory tract and the streptococcus of Herb the parotid and testicle.

The staphylococcus is usually found in circumscribed infections, especially on the surface, while various strains of streptococci produce a great variety of infections and more than any other microorganisms are capable of adjusting themselves to new surroundings by changes of a morphological character and becoming unassailable by the forces of the host.

The streptococcus and pneumococcus in some strains are characterized by infectiousness of a low grade of toxicity. The more virulent microorganisms have a tendency to make their matrix or host less favorable for their growth, while some of low virulence as found in chronic foci make their habitat or soil more favorable for their existence. The plasmodia (hematozoaria) select the red blood corpuscle and Trichina spiralis the muscle.

Likewise toxins have a special selective affinity for certain tissue and produce their symptoms in consequence of such affinity. Tetanus toxins anchor to the motor ganglion and the virus of rabies to the central nervous system. Poliomyelitis anterior is also the result of a specific toxin or microorganism having an affinity for the anterior horns of the cord.

In connection herewith it is of interest to note that some chemical substances localize unequally and thus give rise to certain diagnostic symptoms, for example, the paralysis of the extensors in lead poisoning; also that certain alkaloids, leucomaines, ptomaines, and bacterial toxins may have similar selective effects upon living organisms. Therefore a direct effect upon the cells of the body takes place whenever there exists a mutual affinity between such cells and a toxic substance. Again, tissue cells are sensitized against certain substances; generally as in the appearance of anaphylaxis and locally by limited reaction.

Toxin may act upon a sensitized spot that has held previously injected toxin or its effect for a period of years. This is not unreasonable when we consider that some chemical substances will be fixed in the tissue for a lifetime, for example the common tattoo.

Another interesting chapter recently developed is the acquired specificity for location of certain microorganisms. Like birds that return to their northern home to nest, or like trout that leap to the source of the stream to spawn, so do these microorganisms

*Read before the American Therapeutic Society, Detroit, Mich., June 9, 1916.

when injected into animals race back to the place whence they were taken.

E. C. R. Rosenow (*Journal A. M. A.*, LXV, 20) in an article, Elective Localization of Streptococci, and in a later paper, Bacteriology and Experimental Production of Ovaritis (*Ibidem*, LXVI, 16), gives a comprehensive and convincing discourse on the affinity or tropism, which the streptococci, isolated from various diseased structure, have for the same organ or tissue when injected into animals. In the animals which survived the injections, many showed no other lesion than in the organ or tissue from which the streptococci had been taken. The streptococci strains employed by Rosenow were similar in cultural and other respects, but differed in degree of virulence. Those taken from the gallbladder were more pathogenic than those taken from gastric ulcer, while those from the appendix were least virulent. To use Rosenow's expression, "it appears that the cells of the tissue for which a given strain shows elective affinity, take the bacteria out of the circulation as if by a magnet—absorption."

Beginning with the introduction of bacterial vaccines, when Koch recommended and used tuberculin, we witnessed one reaction after another and failed to take advantage of one important practical application. Koch's tuberculin treatment was then a failure because of misapplication. Time after time was a focal smouldering ember fanned into an active and destructive inflammation because of an overdose of tuberculin.

This focal reaction has presented itself in most every injection we have carefully observed. The flaring up of a boil or carbuncle after administering a suitable vaccine, or the appearance of urethral discharge, frequent urination, or strangury, after using gonorrheal vaccine, or the bursting forth of embryo pimples after the injection of acne vaccine are common observations.

Having these facts in mind, after prolonged treatment of a gonorrheal arthritis, with prostatic massage, irrigation, and carefully measured doses of vaccine, in which there were days of encouragement, though the end result was nil, I decided to give the patient an unusual dose of the vaccine and thus incite an intense reaction in the joints from which he always experienced a great improvement. Within twenty-four hours my patient had a temperature of 103.5° F. with all the symptoms of a general infection. Pain in the affected parts was severe. Interesting and suggestive was the stimulation of an unsuspected focal point of infection resulting in a most distressing epididymitis. The patient informed me at this time of a similar inflammation of the same structure during one of his unpleasant outbreaks over twenty years before. Here, then, was a focal point of infection I had overlooked.

Upon this suggestion of locating focal points by infection by obtaining a reaction following a larger than the therapeutic dose of vaccine, I have been working with a number of cases. Two of these I will report because of their unusual interest.

Case I. A woman of forty years had been treated for gout, rheumatism, and so called "rheumatic gout," with everything from the salicylates and mineral waters to the baking oven and mud baths. She described her suffering as mostly "soft pains, stiffness, joint soreness, and occasional severe joint pains." The heart sounds gave evidence of a previous endocarditis with resulting mitral insufficiency. Cultures made from her blood grew Streptococcus viridans. A vaccine made from this culture and given in an initial dose of 100,000,000 was followed by a moderately severe appendicitis.

Case II. A woman fifty-four years old with chronic polyarthritis and a bed invalid for over a year. She had had pyorrhœa alveolaris and her teeth had been removed while under treatment at the Johns Hopkins Hospital. When referred to me, she was taking from one to two grains of morphine daily and was considered incurable. Three blood specimens were negative or no culture could be grown on either aerobic or anaerobic media. Realizing that this form of infection is usually due to some strain of streptococcus, I injected 50,000,000 bacteria of a polyvalent streptococcic vaccine. In twenty-four hours she was in great distress. "I'm just as sore and painful as a big boil all over" was her remark. Blood specimens taken at this time grew Streptococcus viridans. An autogenous vaccine prepared and given in an initial dose of 100,000,000 was followed by pain and tenderness in the gallbladder region and the usual symptoms of cholecystitis.

The effect of a diagnostic dose of vaccine is both general and local. The symptoms of a general reaction are those akin to a pathogenic invasion—chill, fever, headache, anorexia, general malaise, and increased urination. The local effects, lasting from one to several days and depending upon the size of the dose, are pain and swelling of the affected parts—joints and glands—increased urethral discharge, strangury, or otorrhea as the case may be. In one instance increased discharge in the postnasal cavity determined an infection in the ethmoidal sinuses.

Focal reactions are caused best, if not exclusively, by injection of the killed infecting microorganism, and, as some organisms have a wide range of affinity and adaptability, selection of the vaccine is important.

Inasmuch as the morphology of microorganisms is changed by environment, and a predilection is shown for the organ or tissue in which they have been living, thus establishing an affinity between host and guest, and inasmuch as these microorganisms and tissues thus fixed are unassailable by vaccine made from other strains, why would it not be practical in the absence of a suitable strain to cultivate and acquire this favor by growing the microorganism in a medium containing the extract or substance of the organ we are going to treat?

Forssner (*Nord. Med. Ark.*, 1902) demonstrated that streptococci grown in kidney or "kidney extract acquire a special predilection for the kidney when injected intravenously." Why not apply this principle in the making of vaccines?

Streptococcus viridans, for instance, includes a variety of strains having special affinity for different tissues.

Vaccines and serums prepared with due regard for tropic conditions will, from this point of view be the requirements of the future and, no doubt, many failures today will be successes tomorrow.

The Arlington.

Fatigue Toxins.—L. Ferrannini and S. Fichera (*Riforma medica*, August 28, 1916) from experiments on frogs show that these toxins when injected subcutaneously reduce markedly the extent of muscular contractions, considerably increase the latent period of contraction, shorten and render irregular the curve of muscle fatigue, and lessen excitability, contractility and force of the muscle.

LARYNGEAL ABSCESS.

With a Report of Three Cases,

By Milton J. Ballin, M. D.,
New York.

One of the unusual affections of the throat, occasionally associated with such intense subjective phenomena as to jeopardize the life of the patient, is a phlegmon, or abscess of the larynx.

That this condition is not of more frequent occurrence is surprising when we take in consideration the large number of patients who are subject to repeated attacks of inflammatory processes terminating in localized suppurations in the tonsils, peritonsillar, and retropharyngeal regions. An abscess of the larynx may arise as a primary infection, having its origin in the larynx proper, without any apparent predisposing cause. Or it may develop secondarily to an acute inflammation of the tonsils, nasal, or postnasal structures, and by continuity extend downward toward the laryngeal structures. It is also met as a complication to an old, long standing lesion of the larynx, in that it may develop in rare cases in conjunction with a tuberculous or syphilitic process, and may also arise as a secondary infection of an advanced, broken down malignant lesion.

The inflammatory process having advanced toward the laryngeal area, may involve the submucous layers of the mucous membrane and produce an acute laryngitis submucosa. This condition may, however, under usual circumstances, recede spontaneously, as is generally the case, or it may, in rare instances, lead to the localization of a firm exudate, which in turn may break down into a suppurative process in the form of a diffuse or circumscribed abscess.

An abscess of the larynx, according to most observers, is an infection of adult life, and is never met in infants or young children. According to Vogel (1) it has never been observed as a true spontaneous or idiopathic affection of the infant larynx, but has been observed as a complication, in rare cases, of typhoid fever in children. Parry (2) likewise regarded it as extremely rare in children and reported two cases which, according to him, were the only cases recorded up to 1873. These resembled an acute edema of the larynx in adults, and gave all the evidences of a croup or other laryngeal disease associated with a marked stenosis.

Holt (3) speaks of a submucous laryngitis characterized by a swelling which is partly edema and partly cell infiltration. He does not mention, however, a true form of abscess of the larynx.

Koplic (4) speaks of cases of periesophageal abscesses (retroesophageal abscesses) and also of cases in which pressure of the intubation tube or diphtheria of the pharynx had involved the periesophageal tissue, causing the formation of an abscess. He likewise does not mention the occurrence of a true laryngeal abscess, but states that a retropharyngeal abscess may extend downward toward the larynx and give rise to symptoms there. It is fortunate that in children and infants bacterial invasion usually takes place into the soft tissues of the tonsillar and pharyngeal regions, giving rise to localized suppurations in the form of retropharyngeal, tonsillar, and peritonsillar abscesses, which are easily accessible to operative measures. This same thing applies to adults, for when the suppurative process has become localized in the larynx, it is not merely the collection of pus in the soft tissues, but it is mainly the diffuse infiltration of the surrounding tissue and the varying degree of edema associated with it which give rise to the alarming symptoms.

That suppurations of the larynx were already recognized as far back as the thirteenth century, is evident from the reports of Roland, of Parma, who, at that time, described several cases in which the cause of death was due to laryngeal abscess found post mortem. Furthermore, Morgagni mentions two cases in which the cause of death was unknown, and in which the autopsy likewise revealed an abscess of the larynx. Thus, if we peruse the literature on this subject, we find occasional reference to localized suppurations in the larynx as the cause of death, which, however, were not recognized during life, but were accidentally discovered post mortem.

Thanks to the improved technic of modern laryngoscopy and to the advent of the laryngeal mirror, it has become possible to recognize intralaryngeal pathological conditions in their incipient stages. We are therefore no longer compelled to find, at the autopsy table, an explanation for the sudden death of a patient, but are now able to recognize pathological changes in the larynx before they have advanced to such a stage as to jeopardize the life of the victim. Through the early recognition of intralaryngeal conditions and in particular abscesses, we are enabled in a large number of cases to employ timely and energetic surgical measures, by which it is possible to stay the spread of infection and to prevent the development of fatal complications.

Although cases of laryngeal abscess are occasionally reported (5, 6), they are comparatively rare. Why they do not develop more frequently is difficult to explain. Explanation may perhaps be found in that the mucous membrane of the upper portions of the throat is more prone to traumatic influences, so that the bacteria always present, find ready access, and thus favor the formation of suppurative processes. On the other hand, the larynx, owing to its anatomical position, is less vulnerable and therefore more immune to bacterial invasion.

The etiology of primary laryngeal abscess may be regarded, according to Ziemssen (7), as a phlegmonous inflammation of the submucous connective tissue of the larynx, which may begin as a perichondritis, brought about by a trauma, overexertion of the laryngeal muscles, rheumatism, and catarrhal inflammations, and terminating in a circumscribed formation of pus. Tobold (8) is of the opinion that the primary abscess is merely a circumscribed collection of pus, being the result of an inflammation of the glands of the mucous membrane or of the mucous membrane itself.

Some observers believe that it is brought about by the breaking down of the lymphatic glands or of the bursa mucosa subhyoidea, while others again are of the opinion that the abscess originates in the

tissues of the larynx as the result of some traumatic abrasion, thus creating a port of entry for pathogenic microorganisms.

Any irritation which has a tendency to produce an acute inflammation of the mucous membrane or of the perichondrium, may in short bring about changes in the deeper structures which ultimately result in localized or diffuse suppurations. The primary abscess may develop from external harmful influences as well, so that we find them associated with fractures of the laryngeal cartilages and with injuries of the neck caused by stab wounds, deep lacerations, etc. They may arise after cauterization with acids and caustic alkalies, which have accidentally penetrated into the larynx, or have been taken with suicidal intent; also from the inhalation of pungent, irritating, or hot vapors and gases, and

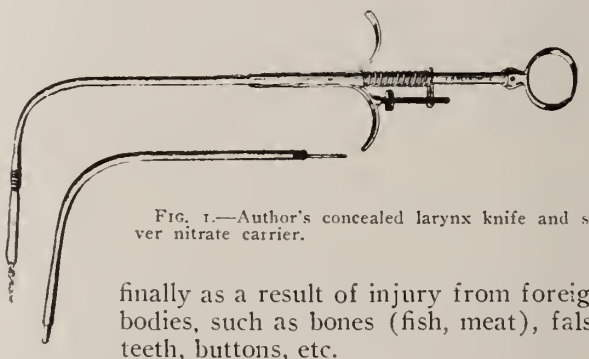

Fig. 1.—Author's concealed larynx knife and silver nitrate carrier.

finally as a result of injury from foreign bodies, such as bones (fish, meat), false teeth, buttons, etc.

The secondary laryngeal abscess may develop from extension of an inflammatory process in the nasopharynx, tonsillar, or peritonsillar region, downward into the laryngeal cavity. It may arise in the course of an acute exanthem, such as measles and scarlet fever, or develop as a metastatic process of a general sepsis, such as a general septicemia (9), a pyemia, an erysipelas, or in rare cases an ulcerative endocarditis. According to some authors, it may occur as a complication to typhoid fever, becoming evident in the convalescent stage; also in conjunction with a tuberculous or syphilitic process which has existed for some time and has undergone degenerative changes.

The site of a laryngeal abscess varies. It may be intralaryngeal or extralaryngeal, and either unilateral or bilateral. In the majority of cases it is unilateral, and may take its origin in the middle of the thyroid cartilage or in the epiglottis itself. It may furthermore become evident as a circumscribed pocket of pus or as a diffuse, widespread suppuration. In the latter form it may extend over the greater portion of the throat, and by penetrating into the deeper tissues, become apparent as a more or less extensive swelling in the neck. In the circumscribed form, however, it remains localized, and is visible as an indurated globular mass. Experience has shown that most laryngeal abscesses take their origin from the lingual surface of the epiglottis, the aryepiglottic folds and in the pyriform fossæ, and that they are usually unilateral, the majority being situated in the left side. Most abscesses are fortunately located extralaryngeally, making the prognosis decidedly more favorable. In the intralaryngeal cases, which are extremely rare, the outlook is unsatisfactory, as the site of the abscess acts as an impediment to respiration, and is inaccessible to operative procedures.

As a rule, a laryngeal abscess runs a rapid course, reaching its acme about the eighth or tenth day, but it may extend over a period of three to four weeks, as in one of my cases. During this time it gradually increases in size until it reaches such dimensions that it either bursts spontaneously or requires surgical intervention to check its further spread. If the abscess cavity is not evacuated before it has advanced to too large proportions, it may cause great distress by pressure and narrowing of the lumen of the larynx, thereby interfering with respiration to such a degree as to jeopardize life.

The prognosis depends on the site of the abscess. This is also more favorable when the condition is recognized early, as it enables us to adopt timely and energetic surgical measures. If the case is one of intralaryngeal abscess, the prognosis is decidedly more unfavorable, as the swelling and edema may proceed with such rapidity that the patient dies of suffocation before medical aid is available. Fortunately, these cases are extremely rare. On the other hand, prognosis is more favorable in the extralaryngeal cases. The infiltration and edema do not progress with such rapidity and do not, as a rule, produce the marked dyspnea during the early stage. It is only when the suppurative process begins to expand that the pressure on the walls of the larynx causes an increase in the edema and a narrowing of the lumen. The extralaryngeal abscess may exist for some days without producing urgent symptoms, and at times has a tendency to expand outward toward the muscular structures of the neck. By doing so the lumen of the larynx remains comparatively free, and the dyspnea does not become very marked. If laryngeal abscesses are recognized in the early stage, and proper therapeutic measures adopted, the prognosis is, on the whole, favorable.

There are cases, however, which terminate fatally. These are fortunately very rare and may be attributed to the sudden development of an acute edema and infiltration, brought about by the rapid formation of the suppurative process.

SYMPTOMS.

The symptoms of laryngeal abscess first manifest themselves as a burning sensation in the throat, which is associated with a feeling of pressure and pain on swallowing. If the abscess exerts pressure against the esophagus, there is more or less interference with deglutition and the patient experiences pain and difficulty in taking food. As the pus formation becomes more diffuse, it gradually brings about a stenosis of the lumen of the larynx so that we notice a change in the patient's voice and an increased difficulty in respiration. The cervical lymphatic nodes become enlarged, and the abscess may be readily palpated as a circumscribed mass on the side of the neck. The spontaneous pain becomes intensified and may be increased by pressure from without. The edema becomes more extensive so that the stenosis produces such difficulty in breathing that the patient is in constant dread of suffocation. As a rule there is no great fluctuation in temperature. There may

be a slight rise between 99° and 100° F. The general condition of the patient is usually good, although there may be a general feeling of malaise and a certain degree of nervous tension and irritability, due more to the fear of suffocation than to lack of sleep and food. The voice becomes more guttural, and talking also requires greater effort. The mucous expectoration becomes more profuse and thicker, and is generally tinged with blood from the highly congested mucous membrane. If the abscess cavity increases in proportion and is under great tension, it may rupture spontaneously, whereupon the patient experiences a paroxysm of coughing, followed by the expulsion of a varying quantity of mucopurulent secretion. If this takes place, there usually follows a great feeling of relief in that the distressing phenomena disappear, the dyspnea improves, deglutition is accomplished with greater facility, and the patient's general condition tends to become more normal.

DIAGNOSIS.

The diagnosis as a rule can be readily made from the sudden onset of the subjective symptoms and from the laryngological picture. Inspection of the larynx reveals a highly congested and turgescent mucous membrane, which is associated with a diffuse or circumscribed area of infiltration. This may have its seat, as already mentioned, in the pyriform fossa, in the aryepiglottic fold, or in the base or body of the epiglottis. The infiltrated area appears as a more or less prominent mass which has a tendency to expand until it reaches such dimensions as to create a mechanical obstruction to the free entrance into and exit of the air from the lungs. As a general rule, the epiglottis is the part most involved, and appears as an indurated mass twice or three times its original size. The edema, which is generally present in these laryngeal conditions, is often a most unpleasant complication. It has the appearance of a globular pearl gray mass, varying in size from a pea to that of a walnut, and usually occupying the upper portion of the epiglottis and its adjacent folds. Its rapid development often endangers the patient's life, in that it occasionally attains within the shortest time such proportions as almost completely to occlude the larynx, causing death by suffocation before medical aid is available. It is not always possible to make a diagnosis of laryngeal abscess at the first examination, as it may easily be mistaken for other pathological conditions. This is especially true if the abscess has existed some time, as in one of my cases, and may under such conditions resemble a gumma, a tuberculous infiltration, or even a new growth.

All these conditions present a marked similarity at first, especially if the abscess is deep seated, so that it is only upon further observation that we notice a change in the picture which allows us to assume that the case is one of laryngeal abscess. On the other hand, if the abscess lies superficially, we can readily recognize its presence by the yellow discoloration of the tense fluctuating area. In such cases incision into this area will immediately reveal the presence of pus. This does not apply to the deep seated abscess, however, for even if we make repeated deep incisions into the indurated area, the pus may not appear for some days, and in some instances it does not come to the surface at all.

In cases of intralaryngeal abscess, repeated examinations may be necessary before we can recognize the true nature of the affection. The recognition of such abscesses is rendered more difficult, if they develop after a syphilitic or tuberculous lesion of long standing, and if they are brought about by the long continued use of an intubation or tracheotomy tube. On the whole, it is not difficult to make the diagnosis of laryngeal abscess, if we take into consideration the sudden onset of the subjective symptoms, in conjunction with the laryngeal picture detailed above.

TREATMENT.

The treatment is at first conservative; we endeavor to allay the pain and feeling of tension and fullness in the throat by local instillations and sprays, and by vigorous application of antiphlogis-

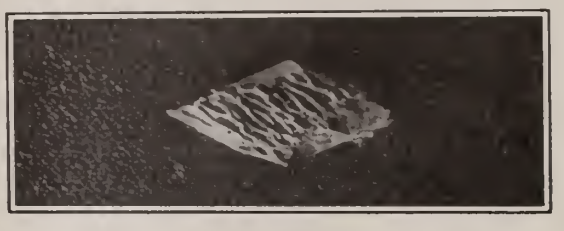

FIG. 2.—Bone, actual size, Case II, Dr. Ballin.

tics. These may be employed in the form of cold sprays to the throat, and cold compresses or an ice bag to the neck. The patient is advised to abstain from hot and irritating food, and is permitted to take only cold, semifluid food. By following this precaution it is possible to ameliorate the subjective symptoms and to bring about a recession of the active phenomena. In some cases this mode of treatment suffices, in that a small circumscribed pocket of pus may either resolve or rupture spontaneously. As a rule, however, such conservative treatment proves ineffectual, and sooner or later the case demands surgical intervention. This applies especially to cases in which the abscess is either a large circumscribed mass or a diffuse infiltration associated with extensive edema. In such cases we endeavor to bring about prompt evacuation of the pus by liberal incision into the indurated area and by free scarification of the edematous parts. To carry this out, we must first thoroughly anesthetize the mucous membrane of the entire pharynx and larynx with a five or ten per cent. solution of cocaine, to which a few minims of adrenaline solution (one to 1,000) have been added. This having been done we proceed, under guidance of the laryngeal mirror, to incise the most prominent portion of the infiltrated area and to scarify the edematous parts as freely as possible with the concealed larynx knife (Fig. 1). If we have been successful in striking the abscess cavity, the patient immediately coughs up a quantity of pus, which is followed by a grateful feeling of relief. If, on the other hand, as happens occasionally, we do not strike the abscess, there is created a point of least resistance at which the pus breaks through some hours later. These manipulations in the larynx, however, sometimes tend to aggravate

the subjective symptoms, the edema becomes more marked, the swelling increases, the larynx fills up with purulent, hemorrhagic secretion and the dyspnea becomes greatly intensified. When this ensues, intralaryngeal surgical measures must again be resorted to, and if the symptoms become too alarming, tracheotomy may even become necessary as a last resort. Intralaryngeal measures having thus been employed, the patient is kept at rest under strenuous antiphlogistic treatment. The throat is sprayed every half hour with:

℞ Acidi borici. ..... gr. x;
Cocainæ hydrochloridis ..... gr. j;
Solutionis adrenalis, 1 ad 1000, ... ℥xx;
Aquæ destillatæ, q. s. ad..... ℥ij.
M. fiat mistura. Sig. Use cold, every half hour.

This is used until there is a diminution in the purulent or mucopurulent secretion and a decided improvement in the subjective symptoms. If the process takes a favorable course examination will, at the end of twelve to twenty-four hours, show great reduction in the indurated area and great lessening, or almost complete disappearance of the edema. Cold compresses to the neck are nevertheless continued, and the patient allowed to take only cold fluid diet (ice cream, cracked ice, etc.) until the subjective phenomena clear up entirely. Internal medication consists merely in giving cathartics and small doses of codeine or morphine to allay pain, which is sometimes intense. If the case runs a normal course, the process, as a rule, subsides within a few days, and the larynx assumes its normal appearance. If intralaryngeal measures have proved futile, and the patient is in danger of suffocation, we must not temporize too long. It is advisable not to try intubation, which is generally not feasible, but rather to perform a rapid tracheotomy. The latter proceeding having been carried out, we can resume intralaryngeal measures with safety.

Finally, we meet with cases of laryngeal abscess in which the pus burrows into the deeper tissues of the neck and becomes evident as a large fluctuating external mass. In other words, we are dealing with a cervical abscess of laryngeal origin. The laryngeal symptoms are not pronounced in these cases, for the larynx remains comparatively free. These abscess formations, being situated rather deep and externally, cannot as a rule be reached by intralaryngeal procedures, so that the most advantageous and safest method of evacuating the pus is by external incision and drainage.

The following three interesting cases which came under my observation are illustrative of laryngeal abscess and are therefore given in detail:

Case I. R. H., a perfectly healthy man, fifty-six years of age, began to complain of pain during the act of swallowing and a feeling of fullness and tension in the throat. This condition persisted for about ten days, during which time he noticed a slight change in his voice and some difficulty in breathing. The sensation of fullness became more marked, and swallowing likewise became more difficult. The patient, being alarmed at his condition, consulted his physician, Dr. M. Schiller, who referred him to me. I found his general condition good, but he was somewhat weak owing to his abstinence from food for about a week. He swallowed cold fluids with difficulty, but found that they had a soothing effect on his larynx, so that he partook of them freely. The patient gave no history of tuberculosis, and there were no lung or throat signs indicative of such a condition. He denied lues infection, so that a Wassermann test was not made. There was no fever to speak of, the temperature ranging between 99° and 100° F. The condition in his throat did not suggest malignancy, as the affection was of acute onset, and there were no other signs, such as emaciation or loss of weight.

Examination revealed a bulging mass about the size of a walnut occupying the left pyriform fossa and a portion of the pharyngeal wall on the corresponding side. The epiglottis, the left arytenoid, and aryepiglottic fold were markedly indurated and edematous. The true vocal cords were not involved, yet there was a slight impairment in speech, which was somewhat guttural; the respiration was labored on account of a slight stenosis and lateral displacement of the larynx. It was difficult to make a diagnosis, at first, and as the patient was in no precarious condition, he was kept under observation for further developments. During the next few days, the edema and swelling became more prominent, the mass increased considerably in dimensions, speech was more impaired, and the dyspnea was very marked. He was ordered to spray the larynx with cold solutions (boric acid, adrenaline solution, etc.) every two hours, and to apply an ice bag to the neck. He was put on cold fluids and given cracked ice freely. This treatment was continued for a week, but the laryngeal condition became worse, so that I concluded that I was dealing with an acute active process, most likely an abscess of the larynx.

I determined, therefore, to make an exploratory incision into the mass. The larynx and pharynx were thoroughly anesthetized with a ten per cent. solution of cocaine, to which a few minims of adrenaline solution were added; with the concealed laryngeal knife the protruding mass in the left pyriform fossa was incised, whereupon the patient coughed up a large quantity of mucopurulent secretion. The edematous parts were also freely scarified, after which there was immediate relief in the subjective symptoms. This operative procedure was performed about 10 a. m. in my office, and the patient allowed to return to his home. In the afternoon, I was suddenly called to his residence, where I found him in great agony and in fear of suffocation. His respiration became so impaired that external operative measures seemed imperative. The laryngeal examination showed that the edema had spread over the greater portion of the epiglottis so that it looked like a large globular mass, almost completely occluding the larynx. Expectoration became more profuse, so that the patient constantly coughed up a foul smelling purulent secretion. Fearing that he might suffocate, and thinking that a tracheotomy might be necessary, I had him immediately transferred to Mt. Sinai Hospital. On his arrival I thought it best to try to relieve his alarming condition by intralaryngeal measures, and if these failed, to perform a tracheotomy as a last resort. Fortunately the former methods proved beneficial; the condition became slightly better; his respiration was less labored, and the feeling of fullness and oppression were somewhat diminished. Antiphlogistics were again vigorously employed with apparent benefit. The purulent secretion became more profuse as the abscess drained freely, and the subjective symptoms showed gradual improvement, so that further recourse to operative measures was unnecessary. The following day inspection of the larynx revealed a diminution in the edema and swelling, and the patient experienced decided relief. From this time on, respiration became more normal, and the laryngeal dyspnea steadily improved, so that by the end of the week the larynx assumed a normal appearance and the patient made a complete recovery. During his stay at the hospital his general condition was good, and his temperature never rose above 100° F. Internal medication consisted merely in the administration of small doses of codeine to allay pain, of which he complained a good deal. As his breath was offensive, owing to the foul smelling secretion, he received inhalations of steam impregnated with a few minims of creasote; these were kept up almost continuously during his stay, and added greatly to his comfort.

Case II. A. H., a healthy robust woman, sixty years of age, came to my clinic at Mt. Sinai Dispensary, complaining of pain in the throat and great difficulty in swallowing. She stated that two days prior to her visit to the clinic she had eaten some meat and had accidentally swallowed a piece of bone. Careful laryngological examination revealed a highly congested and swollen mucous membrane and pronounced induration in the left pyriform fossa. There was a large amount of mucous secretion, so that the

deeper structures of the larynx were hidden. Although this secretion was thoroughly removed, the presence of a foreign body could not be verified. The cervical glands on the left side were slightly enlarged, and external pressure caused considerable pain in the larynx. The sudden onset of the laryngeal symptoms, the laryngological picture of edema and marked induration, led me to believe that I was dealing with an acute abscess of traumatic origin. She was ordered to spray her throat with cold solutions (as in the previous case) every three hours, and put on a soft cold diet. The breath being offensive, she was given steam inhalations containing compound tincture of benzoin, every four hours.

Two days later, she returned to the clinic in much worse condition, as her laryngeal symptoms had become greatly aggravated. Her voice was impaired, dyspnea had developed, and deglution was difficult and painful. Examination of the larynx showed that the indurated area had extended, and that the epiglottis was swollen and edematous. There was no sign of a foreign body, as it was lodged deep in the pyriform fossa and hidden by the infiltrated mass.

The pharynx and larynx were thoroughly anesthetized with a ten per cent. solution of cocaine, to which a few minims of adrenaline solution, one in 1,000, had been added; with the concealed laryngeal knife the indurated area was incised, whereupon a quantity of foul smelling pus was expelled. The edematous parts were scarified and relief followed. The patient was permitted to return home and told to continue the antiphlogistic treatment. For the next few days, a large quantity of pus was expelled. The dyspnea improved, the pains diminished, and swallowing was accomplished with greater ease. During the night she had an attack of coughing, and to her astonishment expelled a hard mass, which proved to be a piece of bone (Fig. 2). From this time on, the subjective symptoms improved rapidly, so that by the end of the week the larynx assumed a normal appearance and recovery was complete.

Case III (under the care of Dr. H. D. Mandelbaum, and seen by me in consultation). A. F., young lady, was suddenly taken ill with fever, discomfort in throat, and severe pain on swallowing. The subjective symptoms became so intense that the brother of the patient sent for Doctor Mandelbaum at one o'clock in the night. Examination revealed a slight congestion and reddening of the tonsillar and pharyngeal regions and an enlargement of the left cervical nodes. She received small doses of salol and was ordered to gargle with antiseptic solutions every hour. She was seen again on the following morning, at which time the subjective symptoms were somewhat exaggerated, and a few irregularly scattered white spots could be seen on the left tonsil. The temperature was not high, ranging between 99° and 100° F. She felt miserable, however; the dysphagia had become more painful and there was, in addition, a beginning sense of suffocation. Owing to an increase in the subjective phenomena, and the respiration becoming impaired to such a degree that the patient was in utter fear of suffocation, Doctor Mandelbaum was again summoned during the night. Examination of the larynx revealed infiltration of the left lateral pharyngeal wall, which extended down into the left pyriform fossa and was associated with extensive edema of the epiglottis and surrounding tissue. This picture suggested to the doctor that he was dealing with an acute laryngeal suppuration, and therefore deemed it advisable to incise the mass. This incision was followed later by a scant purulent discharge, which gradually increased during the following day. The patient received vigorous antiphlogistic treatment, in that she was directed to spray the throat with cold antiseptic solutions, to take plenty of cracked ice and cold liquids, and in addition to apply cold compresses to the neck. The patient being in a very nervous condition, and the subjective symptoms showing but slight improvement, I was asked to see her in the evening with Doctor Mandelbaum. She still had great pain and difficulty in swallowing, and her breathing was considerably impaired. There was a feeling of fullness in the throat, and constant fear of suffocation. There was profuse mucopurulent secretion, which was being freely expelled. Examination showed diffuse induration in the left pyriform fossa which extended upward and was associated with extensive edema of the epiglottis and surrounding tissue, so that the larynx was narrowed down to a small cleft. Through the incisions made by Doctor Mandelbaum at different parts of the mass, pus could be clearly seen to escape. Drainage was apparently free, so that further operative measures were deemed unnecessary. The patient was advised to keep up the sprays and gargles and to continue the cold fluids and compresses to the neck. During the subsequent twenty-four hours the mucopurulent secretion was abundant and the swelling and edema gradually subsided, so that within a few days all subjective symptoms disappeared, the larynx assumed a normal appearance, and the patient made an uneventful recovery.

These three cases are clear examples of laryngeal abscess, in which the localized suppuration was situated, as in the majority of instances, on the left side, and in which complete recovery ensued after timely intralaryngeal measures. The main purpose in presenting this subject is to call attention to the infrequency of this laryngeal affection and to emphasize the fact that if it is recognized in time and urgent intralaryngeal measures are adopted, alarming complications can be prevented, and a satisfactory outcome can be obtained in the majority of cases.

LEIOMYOMA OF THE PYLORUS.

By Joseph R. Eastman, M. D.,
Indianapolis;
And Harry K. Bonn, M. D.,
Indianapolis.

Since the stomach is the primary seat of approximately two thirds of all gastrointestinal carcinomata, it follows that the diagnosis of any tumor of the stomach is especially important in patients at the cancer age. For this reason we have deemed this case of leiomyoma of the pylorus of sufficient interest to justify its report, as it directs attention to benign neoplasms of the stomach occurring during the cancer age. In a fairly comprehensive review of recent literature it was interesting to note how meagre is the information relative to benign neoplasms of the stomach compared with the ample literature concerning ulcers of all types and carcinomata.

One of the most recent papers dealing with benign tumors of the stomach is that by A. MacK. Campbell. Campbell states that the extreme rarity of reported cases is astonishing, many clinicians of wide experience having never observed a case either in the living or on post mortem examination. Campbell cites Tilger as reporting only fourteen benign tumors of the stomach in 3,500 autopsies. In 7,500 necropsies at the Obuchow-Krankenhaus, four cases of gastric polyp were found.

Benign tumors of the stomach may develop in any part and may arise from any of the three gastric coats. They vary in size from a pea to a fetal head. The usual variations as regards pedicle formation obtain. With subperitoneal myomata a small pedicle is usually present. While there are twelve to fifteen varieties of benign gastric tumors, myomata are the most common. There are forty authenticated cases

of gastric myomata on record. Frequently such myomata prove themselves to be malignant, showing areas of fibrosarcomatous or myosarcomatous degeneration (Campbell).

Mallory and Borst believe that leiomyoma of the stomach is second in frequency to carcinoma, and that in only rare instances does the leiomyoma grow rapidly and metastasize. Myomata are usually situated near the pylorus and may be single or multiple;

Fig. 1.—Photomicrograph showing entire encapsulated tumor of pylorus in submucosa. (Shapiro, Baltimore.)

they rarely exceed a hazel nut in size and are composed of nonstriated muscular fibres.

Borst, in discussing leiomyoma, says that "these tumors develop in their usual form, as circumscribed, spheroidal, or as tuberous lumpy growths, which are separated from the surrounding tissue by a layer of connective tissue, and for that reason can be shelled out easily and completely." These tumors are for the most part not pure, those of mixed muscle and connective tissue being called fibromyomata. Pure leiomyomata appear oftenest in the stomach and in the intestinal canal, and also in the testicle and the region of the nipple.

Since the muscle fibres are bound together in bundles and strings which stretch in all directions, these new growths have a fascicular arrangement in which figures such as curls and waves are conspicuous. Leiomyomata resemble fibromyomata in the gross and they are frequently confounded. The leiomyoma is throughout benign; metastases are extremely rare. The leiomyoma often appears in pure form in the intestinal tube, in the esophagus, stomach, and intestine. These tumors are situated, according to Steiner, interstitially just under the serosa and under the mucous membrane and are often multiple. Steiner says that "intestinal myomata are of more frequent incidence than stomach myomata."

Submucous myomata of the gastrointestinal tract, according to Birch-Hirschfeld, form the predisposing cause of intussusception, and subserous myomata of the intestine may lead to diverticulum formation. Steiner and Böttcher observed myoma developing from the hypertrophied musculature of the gastrointestinal canal. Lübarsch and Cohen showed, in two cases of stomach myoma, that the tumor developed from the musculature of bloodvessels. In another case they found pancreas lobules and a well developed pancreatic excretory duct in a myoma of the stomach suggesting a congenital predisposition.

Hansemann and Schmorl found a very diffused myoma of the stomach which had established metastases in the liver and pancreas. Among the retrograde changes of myoma of the intestinal tract, Cohen observed fatty degeneration, edematous softening, calcification, and also hyaline degeneration of the musculature. Sarcomatous intestinal myomata have also been observed. Babes and Nanu believe sarcoma to be derived from muscle elements. Steiner, on the other hand, believes such sarcomatous myomata to be derived from interstitial connective tissue.

Fr. Henke, *Praktische Anleitung zur Untersuchung von Geschwulsten,* says that smooth muscle fibre tumors are usually found where tissue of this kind has previously existed. Henke speaks of combination forms, including leiosarcoma in which well developed smooth muscle elements are found along with polymorphous irregular sarcoma cells. He believes that sarcoma cells are derived either from the interstitial connective tissue or by transition of the smooth muscle fibres themselves. He notes the interesting finding of gland inlays in smooth muscle tumors of the stomach noted by Lübarsch (*Ergebnisse der Pathologie,* VI, 1901). He calls attention to the possibility of the epithelium of these gland inlays undergoing change to atypical forms of epithelium, i. e., to the epithelium of carcinoma.

Campbell makes the significant statement that frequently it is impossible or practically so, to differentiate these benign tumors from carcinoma or sarcoma except by a most painstaking pathological examination. In our search of the literature of benign neoplasms of the stomach in only one instance were

Fig. 2.—Low power photomicrograph showing details of central portion of tumor. Fibres cut in transverse and longitudinal section. (Shapiro, Baltimore.)

we able to find a reported case of leiomyoma confined to the pylorus. Henke (*Mikroskopische Geschwulstdiagnostik*) gives Lübarsch as the reference for this case. The report of our case of leiomyoma of the pylorus is as follows:

Case. Man, fifty-eight years of age, white, of German extraction, was unable to recall disease of any severity which

he had had up to his present illness. Family history: As far as the patient knew, there had been no cancer, tuberculosis, lues, or insanity in his family. He was questioned as to whether he had ever had typhoid, pneumonia, and the other commoner diseases of this climate, but it appeared that he had been singularly free from any previous illness. The patient had never complained of the commoner symptoms of indigestion, had never had nausea nor vomiting, and had had no pain bearing any definite relation to the taking of food before the present trouble became manifest. Neither had he ever passed blood by the bowel, to his knowledge.

Present illness: Admitted to the hospital in the service of Dr. J. R. Eastman, February 15, 1916. At the time of entrance he stated that he was unable to eat or drink without immediately regurgitating what had been previously swallowed. This inability had begun suddenly about February 1st. Previously he had not experienced difficulty in swallowing, and he insisted that the onset of this trouble was acute. He made no distinction as to the character of the food or drink as regards his inability to retain them. He was quite sure that he had never vomited blood or that the regurgitated fluids had even been blood streaked. He was positive he had never had blood in the stool. Again questioned, on the day following, particularly as regards an increasing difficulty in swallowing and subsequent regurgitation which had persisted for some time, he was positive that previous to February 1, 1916 (two weeks before admittance to the hospital), there had never been any such difficulty.

Physical examination: Was a spare, poorly nourished man, with flabby musculature, weighing 110 pounds, five feet seven inches in height; stated there had been a loss of fifteen pounds in the last two weeks, because he had had practically no nourishment.

Pulse was 80 a minute, of good quality, but the arteries were somewhat sclerotic. Heart tones were normal; no murmurs and heart not enlarged. Lungs clear; a slight cough with scanty expectoration. Four subsequent examinations of the sputum were returned as negative for tuberculosis. Had a lax, thin abdominal wall with flabby musculature; no points of tenderness in the abdomen, except immediately below the sternum. At this point or a little higher, said he perceived a blocking or stoppage of ingested food or drink. Also at this point, some muscular rigidity was demonstrable. The hooked finger test revealed no tenderness of the gallbladder. Percussion revealed a normal liver. Palpation of the appendicular region elicited no tenderness. The large bowel was slightly tympanitic.

Five different uranalyses were made, only one of which showed any abnormality, this one specimen exhibiting a slight trace of albumin. The specific gravity ranged from 1015 to 1022. Microscopical uranalyses were negative. X ray screening and plating were done after the administration of barium buttermilk. The radiographer reported that both plates and screening showed a stricture of the esophagus four to five inches above the cardiac orifice of the stomach. Immediately above this stricture there was a decided ballooning of the esophagus for two or three inches. It was also noticed during screening that a thin stream of the barium had finally found the way through the stricture. The radiographer made a diagnosis of benign esophageal stricture.

TREATMENT.

Since the patient appeared to be weak, three nutritive enemata a day and proctoclysis of one pint of water twice a day were ordered at once. Under this nourishment he appeared to recover his former strength rapidly, and at the end of one week was deemed sufficiently strong to withstand a gastrostomy.

When the abdomen was opened the usual examination of the upper abdominal organs was made and resulted in the finding of a hard, fairly movable tumor the size of a small walnut in the anterior wall of the pylorus. The edges of this tumor were fairly smooth, nevertheless it felt distinctly hard to the touch. The surrounding lymph gland areas were carefully palpated for enlarged glands, but this search proved absolutely negative. The finding of such a tumor in the pylorus of a man fifty-eight years of age suggested early carcinoma without glandular metastases.

Thus it was deemed proper to do a pylorectomy followed by a posterior no loop gastroenterostomy (Billroth No. 2). A Witzel's gastrostomy was also done. The removed pylorus was at once sent to the laboratory for a frozen section. A report of carcinoma was returned in fifteen minutes.

The patient recovered from the anesthesia without incident, and his preoperative nutritive enemas and proctoclysis were begun again. After the fourth day, milk was introduced into the stomach every three hours through the gastrostomy tube during the day. After the seventh day, broths and other liquids were given in the same manner. On the eighth day, the patient found that he could swallow

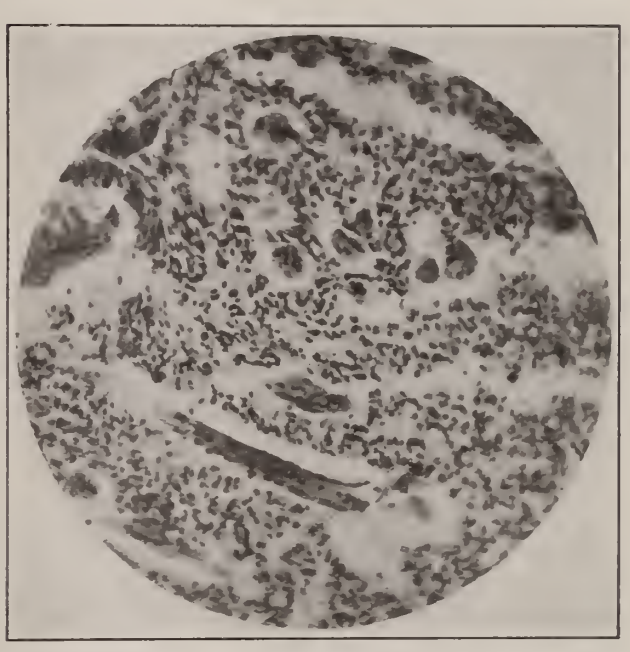

FIG. 3.—High power photomicrograph showing transverse and longitudinal section of tumor elements and of capillary vessels, imperfectly formed. (Shapiro, Baltimore.)

water easily and without the slightest disposition to regurgitate. On the tenth day, milk was given by mouth and retained.

It became necessary, about the seventh day, to irrigate the stomach through the tube with warm water previous to each administration of milk or other fluids because of a moderate quantity of bile which had entered the stomach. The stomach was washed out with warm water until the returning fluid was clear, and the food was then permitted to run into the stomach by gravity alone after the stomach lavage before each feeding. No further difficulty was experienced. The patient had a formed stool on the seventh day after operation. At no time was it deemed necessary to give a cathartic.

Gross pathology. The specimen consisted of a fresh pylorus three and one half inches in length. In one wall of the pylorus there was a nodule the size of a small walnut. This nodule was hard, fairly movable, and with smooth borders. The cut section of the pylorus extended at least one and one half inch in each direction from the

centre of the tumor. When the surrounding tissues were incised, the tumor, which was apparently encapsulated, was expressed cherry seed fashion. The pathologist who sectioned the tumor remarked upon the facility with which the tumor had popped out of its bed when he incised the overlying tissues. The tumor itself appeared quite hard, and was smooth in outline and without irregular edges. There was a fairly broad pedicle.

Microscopical pathology. The tumor was sectioned later by Dr. H. R. Alburger, formerly professor of pathology in the University of Indiana, whose report was as follows: "The section is taken at right angles to the surface and shows well the mucosa, submucosa, muscularis, and serosa. All of these coats are relatively normal, but there is shown to exist in the submucosa a neoplasm, made up of a distinctly typical tissue. The new growth is apparently growing from a central focus from which the bloodvessels, which are very conspicuous and of thin walled type, radiate. The growth is thus seen to be many lobed, each lobe with central blood supply, around which the characteristic tumor cells are growing. These cells are uniform in morphology and are elongated with long rod shaped nuclei of nonvesicular type. The interstitial tissue is small in amount. Diagnosis: Leiomyoma.

The possibility has occurred to me that the cells of this growth might have originated from the perithelium of the bloodvessels, but they do not correspond with any other example of perithelioma that I have seen."

A section was also submitted to Dr. Emil Ries, of Chicago, whose report is as follows: "After looking over the slide which you kindly sent me, I have reached the conclusion that it is a leiomyoma without any indication of malignancy."

CONCLUSIONS.

1. Benign neoplasms of the pylorus, especially the myomata, may simulate early carcinoma.

2. Even though the patient has reached the cancer age, benign neoplasm cannot be excluded.

3. Careful sectioning and study of benign gastric neoplasms is necessary for correct diagnosis.

4. The frozen section method cannot be considered an infallible method of diagnosis in this type of neoplasm.

GRAVID UTERUS DUPLEX.

By W. R. Jackson, M. D., F. A. C. S.,
Mobile.

Double uterus is so frequently reported that an enumeration of the cases would occupy several pages. Two horn, bipartite, duplex, and double uteri are so called according to the extent of the duplication. The varieties are numerous and differ in degree, some having a partition (partite) dividing the uterus into symmetrical halves, others are slightly bicornate, and still others are more divided where the rudimentary halves or horns remain more or less separate instead of coalescing through their whole length. The variety of double uterus in which the duplicate formation affects the whole organ is known as Uterus bicornis duplex; in this kind there are two distinct uteri, each having its own cervix and fundus and separate annexa (tubes and ovaries); usually each uterus has only one tube and ovary. Again, the type that has two bodies and one cervix, being the most frequent, is termed Uterus bicornis unicollis, whereas, if there is no connection between the halves of the organ, there being two distinct uteri and two separate vaginæ, it is termed Uterus duplex separatus.

Numerous cases of pregnancy have been reported in patients with double uteri. Morand, Bartholinus, Tiedmann, Ollivier, Blundell, and many others relate instances of double uterus in which impregnation had occurred, the fetus being retained until full term.

When there is simultaneous pregnancy in each portion of a double uterus, complication of circumstances may arise. Debierre reported a case of a woman who bore one child on July 16, 1870, and another on October 31st of the same year and both at full term. She had only three menstrual periods between her confinements. The question in this case would be: Was this superfetation in a normal uterus, or was there a double uterus? There would be in this case the possibility of one of the children undergoing protracted gestation or the other having a premature birth. Voight and Thilow have reported cases of triple uterus. My cases follow:

Fig. 1 (Case I).—Gravid uterus bicornis: A, blood clot; B, fetus; C, constriction of cervix.

Case I. Female, white, married, aged nineteen years, nullipara, complained of severe pains in abdomen and pelvis. The patient was well nourished, weight 120 pounds. Menstruation had been regular until four months ago, at which time it ceased. Examination by abdominal palpation revealed a large nodular mass in the hypogastric region. Vaginal touch revealed a boggy mass. After four weeks another examination demonstrated that the swelling had not materially increased. The patient was suffering intense pain and demanded surgical relief. On May 4, 1899, median laparotomy revealed two large tumors, about four inches in transverse diameter and six inches in the long diameter. Upon palpation of these two masses, semifluctuation was present, and both were of the same dark purple color. It was a question to me if pregnancy was present with a soft fibroid or some other tumor. Further examination showed that the masses joined each other at their lower or pedicle extremity, and that each had a normal tube and ovary attached to its upper and outer angle, thus clearly indicating that a double or bicornate uterus existed. I decided that an exploratory incision was the only way that I could determine the nature of the two bodies.

Incision into the mass on the right side showed a sac full of old congealed blood; this was scooped out and it was noted that the lower pedicle portion was obstructed, there being no outlet to the vagina except a filiform one. The conclusion was readily

reached that the contents of the sac was old retained menstrual blood, dammed up by the cervical obstruction, and this would easily explain the cessation of menstruation four months ago. The mass on the left side having exactly the same appearance as that on the right side, was diagnosed as a similar condition. This tumor (?) was removed as in amputating a cervix. The other mass was likewise removed without opening it, and both stumps were treated by closing suture. The left mass was opened after removal, and behold! there was a four months' fetus. Attached to the cornu of each mass, as stated above, were a tube and ovary. These were left intact. If a diagnosis of pregnancy in the left cornu had been made unequivocally, it would have been proper to remove the right and leave the left uterus for complete gestation. It is now conceded to be good surgery or gynecology always to remove one of the cornua of a duplex uterus, especially in young women, so that there will be plenty of room to permit development of the gravid cornu.

This patient made an uninterrupted recovery and

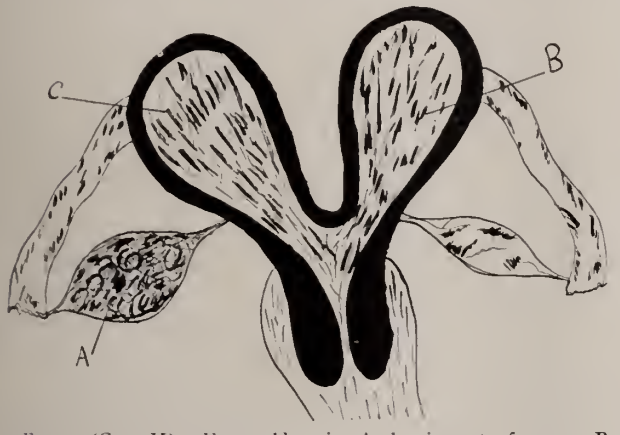

FIG. 2 (Case II).—Uterus bicornis; A, hemic cyst of ovary; B, left cornu; C, right cornu.

is now well and happy in the knowledge that she is rid of her double uterus.

CASE II. Female, colored, schoolteacher, aged twenty-eight years, single; menstruation began at the age of eleven years and continued regular. Not very well nourished, weight 118 pounds, this patient applied for examination and treatment because of severe pains in the lower abdomen and pelvis, which were always augmented during menstruation.

Physical examination by abdominal palpation showed tenderness in each iliac fossa, more severe on the right side, where a mass the size of a small apple could be felt; no mass on the left side could be palpated. Vaginal digital palpation revealed masses on both sides which were fixed and tender on pressure. The cervix was normal and could be felt in the median line. Speculum examination demonstrated a normal cervix with some mucous discharge. The diagnosis was salpingitis, cystic ovary on the right, and adherent appendix.

Operation (laparotomy) on June 14, 1916, disclosed the following conditions: A two horn uterus, each being normal in size and having attached to each upper angle a tube and ovary. The ovary on the right side was one large hemic cyst the size of an apple, that on the left side normal. Both uteri were in retroversion, and united at the cervix into one large neck with the bladder folded in between the cornua and behind the cervix. The appendix was glued behind to the cecum.

The appendix was removed, the two uteri were suspended by their round ligaments (Gilliam), and the cyst was removed. Both uteri were preserved in order to follow the case in the future as to pregnancy.

164 ST. MICHAEL.

TUBERCULOSIS OF THE BRONCHIAL GLANDS.

BY MARY E. LAPHAM, M. D.,
Highlands, N. C.

The symptoms of tuberculosis of the bronchial glands are caused by the absorption of toxins and by pressure upon adjacent structures. Unless there is sufficient absorption of toxins, there is no marked toxemia; if the mediastinal structures sufficiently adapt themselves to the gradually increasing size of the glands, there may be no pressure symptoms. In these cases there is nothing to attract attention to the bronchial glands, the diagnosis is not made, and the future developments depend upon whether the processes become thoroughly sclerosed, remain potentially active, or become aggressive and prove dangerous by erosion of the esophagus, trachea, bronchi, and bloodvessels; by inducing pathological changes in the lungs, leading to the development of tuberculous processes, or by direct extension from the bronchial glands into the lungs.

The syndrome of tuberculous toxemia is the same as that from the lungs. The septic manifestations, the pulse, temperature, chills, and sweats are the same as in other septicemias; in the less violent types the septic symptoms do not appear; there is a tendency toward concealment, although the pulse and temperature may be sufficiently characteristic to lead to the correct diagnosis.

The pulse is usually increased in frequency and softer, but cases are found with a pulse of sixty and full pressure. A pulse of ninety-six, with lack of strength and a history of inability to work is suspicious. The relaxed tone of the vasomotor system, the lowered blood pressure, the insufficiency of the myocardium, the pressure upon the cardiac branches of the vagus, the chlorotic anemia and dyspnea, and the fever combine to increase the frequency of the pulse and to make it abnormally unstable and easily affected.

The fever as a rule is not high, frequently not over 99° F. According to Philippi it is usually under 38° C. and very labile; a slight cold or a little more effect of any kind, physical, mental, or emotional, is apt to send the temperature up; often there is a regular rise before or during menstruation. "Fever from the bronchial glands is harder to overcome than that from the lungs; there is a tendency to persist for years and it is very probable that most of the cases of chronic and intermittent fever with negative clinical findings are caused by tuberculous processes in the bronchial glands." (1).

We have found that many cases are subnormal. According to Lucas the temperature is very irregular and as apt to be below normal as above. There is often a morning rise in temperature, making the patients feel depressed in the morning and very irritable and weak, while they are better and

stronger toward night because the fever has passed off. Malaria and typhoid are often diagnosed from the temperature, especially when there are no physical signs in the lungs.

Sweats are not as common as the general relaxed tone of the vasomotor system. There is a tendency toward increased dilatation and permeability of the vascular walls, shown in the lowered blood pressure, the exudative diathesis of Czerny, eczemas, erythemas, flushings, cold, clammy hands and feet, chillblains, etc. We have had cases of circumscribed erythema, especially in the interscapular region, which were markedly aggravated by tuberculin, menstruation, indigestion, physical efforts, and alcohol. Sometimes the erythema is over the trapezius and associated with the stiff neck symptomatic of concealed tuberculous processes in the bronchial glands.

The hematopoietic system is functionally depressed, and it may be that the oligochromemia or chlorotic anemia is largely responsible for many of the characteristic consequences of tuberculosis of the bronchial glands. The blood and clinical findings typical of chlorosis correspond very closely with those of tuberculosis. There is the same inability to produce enough energy; the same lack of muscular force; even if the will and desire for work are spared, there is not the strength for the persistent effort necessary to accomplishment. Often there is an indifference, a lack of interest in everything requiring effort. It is even possible that this fundamental weakness is somewhat responsible for the craving for alcohol, or for something to lift one up and to put some force into existence. Chlorotics are easily depressed and stimulated; feel bad in the morning and better toward night; get out of breath when walking against the wind or up a slope or carrying weights or talking; the dyspnea may be annoying and associated with pain around the heart or a stitch in the side. The cherry red lips contrast with the striking pallor; or the coloring may be brilliant and clear or sallow like soda biscuit; the nervousness, "stomach troubles," constipation, headache, "biliousness" are all well known chlorotic manifestations equally characteristic of tuberculosis which should receive careful study to determine whether there may not be a tuberculous foundation; this is especially true of young girls approaching maturity and young women. In answering this question, it is well to remember that tuberculosis of the bronchial glands cannot always be detected by a physical examination of the lungs, but may require its own methods for diagnosis.

The functional depression of the hematopoietic system and the toxemia amply explain the malassimilation and malnutrition characteristic of tuberculous processes; in the newly born and yearlings marasmus may result or rickets be favored (Wiener, 2). Hitherto apparently well infants, sound and well nourished, cease to gain weight; at first this is the only sign and the child seems well enough, but gradually the *habitus tuberculosis* of Pollak develops or in older children the *habitus phthisicus*. The pretuberculous or tuberculizable child does not develop normally. Infantilism, juvenility, the lymphatic diathesis, the slender frail form, the disproportionate growth of hair, a juvenile pelvis and genitalia all manifest the inhibition of development. The functional depression of the nervous system varies from the fretful irritability of weakness or sluggish lack of ambition and interest to pronounced neurasthenia and even hysteria. Again and again adult patients tell us that they knew a long time before they broke down that something was wrong because they did not feel right; there was a lack of nervous force; the general consciousness of something wrong is often sufficiently strong to force attempt after attempt to discover the flaw; often and often there is a deep, innate fear of tuberculosis; often one doctor after another is consulted because the instinct of the patient is not satisfied with negative findings; often the comforting assurance that there is nothing the matter and no cause for anxiety because nothing can be found in the lungs is based merely upon a physical examination of the lungs, and the possibility of tuberculous dangers is excluded without estimating the condition of the bronchial glands, although it is well known that in the majority of cases tuberculosis of the lungs is secondary to that of the bronchial glands. Vasomotor changes, chlorosis, neurasthenia, hysteria, impaired cardiac force, gastrointestinal disturbances, and menstrual irregularities are logical consequences and symptoms of tuberculosis of the bronchial glands and should never be accepted as primary conditions without a careful study of the mediastinum. Neuritis or polyneuritis may be the first manifestation of tuberculous toxemia; the spinal cord and the brain may suffer and sexual desires be stimulated; the toxins of closed foci are especially absorbed by the nerve tissues, and this absorption does not tend to lessen, corresponding to the improvement in the tuberculous lesions (Mircoli, 3).

The child or man may run the whole gamut of digestive disturbances, from a feeling of discomfort and distress or sensation of fullness after meals to the acid pains of hyperchlorhydria or gastric ulcer and the paroxysms of tabes; menstruation is especially disastrous, causing vomiting or spitting up of food after meals and loss of weight. The constipation is obstinate from lack of peristalsis; the headache and stiff neck are very painful.

Menstruation is apt to be irregular, either too frequent and excessive, or delayed and scanty, or entirely suppressed. Graefenberg (4) says: "Nearly all cases of primary dysmenorrhea are undeveloped sexually; the genital system resembles the infantile type and the tuberculous foundation may be revealed only by tuberculin reactions. We should, therefore, pay less attention to chlorosis and anemia as primary etiological factors and more to tuberculosis; instead of operative interference in the pelvis, which is often useless and harmful, we should first try the effect of tuberculin, which in many cases proves strikingly successful."

We have found this advice of Graefenberg's amply confirmed by our experience. A young woman of twenty-two years began spitting up her food after meals: there was lack of strength and appetite and loss of weight; the rest cure and feeding was faithfully tried without improvement; the x ray showed enlarged bronchial glands and peribronchial infiltra-

tion of the right lung; minute doses of tuberculin overcame the nausea and spitting up of food. We have come to consider menstrual disturbances of any kind, or a general exaggeration of any morbid factor at the time of menstruation, as warranting a thorough examination of the bronchial glands.

In tuberculosis of the bronchial glands there is always the possibility of erosion and perforation of the esophagus, trachea, bronchi, and bloodvessels. Usually this danger is not announced by preliminary manifestations pointing to its approach. The children seem well, and the catastrophe occurs without warning or without the clinical signs being understood. In penetration of the esophagus, as reported by Kelling (5), the patients were young adults inclined to "scrofula"; there were no symptoms to attract attention to the tuberculous processes in the bronchial glands until perforation of the esophagus occurred and crumbling, evil smelling masses were expectorated. In these cases the clinical signs pointed to gastric ulcer; there was also pain in the larynx, laryngospasm, and irritation and even paralysis of the vocal cords; there was pain behind the manubrium and some difficulty in swallowing, as the mouthful of food would stick in the esophagus for a moment before it passed the point of stenosis.

PRESSURE SYMPTOMS.

The tracheobronchial glands begin in the superior mediastinum and follow the trachea and bronchi down through the anterior, posterior and middle spaces on into the lungs. Behind the sternoclavicular articulation, extending down to the bifurcation of the trachea, the group known as the retrosternal glands of Zuber are in intimate relationship with the venæ anonymæ and the origin of the superior vena cava just behind the first rib and in front of the right border of the trachea, whence it descends almost vertically to the heart. This retrosternal group is often enlarged and often presses upon the superior vena cava. "Among the great vessels, aorta, arteries, and pulmonary veins, azygos veins, and superior vena cava, it is precisely the latter which is most often compressed on account of its immediate connections with the mass of tracheobronchial glands of the right side which are called the sternoclavicular glands." (Zuber, 6.) According to Rach (7), this compression of the superior vena cava, which in exceptional cases may even amount to obliteration (Tonnele), may cause intermittent cyanosis and edema of the face or even edema of, and hemorrhages into the meninges. It is probable that this compression of the superior vena cava may have something to do with the rapidly fatal cases of cyanosis, dyspnea, unconsciousness, and death so typically fatal in the bronchial gland tuberculosis of infants. It is also possible that the stasis in the meningeal circulation explains the association of tuberculosis meningitis with that of the bronchial glands, which was commented on by Strauss (8) in 1895. Pettentati (9) reports a case of obliteration of the superior vena cava by a thrombus from caseous mediastinal glands. Mancini (10) reports twenty-one cases of tuberculous meningitis of children; fourteen were under three years of age, seven under six, all were secondary to tuberculosis of the bronchial glands; in three cases there were solitary tubercles in the brain. Rossle (11) reports a case of diffuse tuberculous basilar meningitis in which there was considerable sclerosis with half caseated and half scarred lesions. Upon the base of the brain, from the chiasma across the pons to the medulla, there were many conglomerate tubercles and also in the cortex of the hemispheres and the choroid plexus; the superior surface of the cerebellum was covered with thick, grayish, yellow, caseous grandulations; the only other tuberculous focus in the body was in the enlarged bronchial glands.

Pollak (12) calls attention to the fact that in the tuberculous meningitis of children there are few suggestions of tuberculosis of the bronchial glands; as a rule the meningitis attacks children in apparently good health, and without the knowledge acquired at autopsies there would be no reason for suspecting that meningitis may be secondary to absolutely concealed tuberculous processes in the bronchial glands. Autopsies teach us that this association always exists, and it is inferred that the rapidity of meningeal processes leaves no time for slower developments. Goodman (13) in his paper on Lymph Node Rupture says:

> The digestive type starts in with fever and vomiting, followed by difficult breathing, cyanosis, unconsciousness, and death. In quite a few instances when the digestive type of symptoms is presented, there is also marked meningeal irritation, and from the symptoms which the child presents it is impossible to differentiate between this form of meningismus and a true meningitis. The more I see of these cases, the more I am impressed with the fact that a great many of the so called gastrointestinal disturbances with meningeal symptoms are often cases of mediastinitis with local suppuration and absorption rather than true intestinal toxemias.

Rach says that children with tuberculosis of the bronchial glands may remain apparently perfectly well and vigorous until all at once complications like suffocation and meningitis suddenly develop. Kraemer (14) compares the effects of pressure by enlarged bronchial glands upon the intrathoracic vessels with that of enlarged cervical and inguinal glands upon the vessels with which they are associated, and says: "Just as enlarged inguinal glands cause edema of the external genitalia and lower extremities, and enlarged cervical glands cause edema of the face and dilatation of the veins of the nose and face, so the mediastinal glands may cause pressure upon the return circulation from the head and the surface of the chest, causing cyanosis and edema of the face and hands and feet, unilateral dilatation of the veins of the face and neck, and over the surface of the chest." According to C. Weigert, the pressure of caseating bronchial glands upon branches of the pulmonary veins may cause their erosion and penetration, resulting in acute miliary tuberculosis, or hemorrhages. Pressure upon the walls of the bronchi or upon the trachea may obstruct the circulation, causing engorgement and rupture, with consequent spitting of blood and hemorrhages. It has been difficult to explain hemoptysis and hemorrhages persisting for some time, even for years, with no physical signs in the lungs and nothing to account for them, but hereafter the Röntgen ray showing the enlargement of the bronchial glands may explain them.

There is nothing more puzzling to the physician

than the spitting of blood without apparent reason. This may be due to the pressure causing a vessel in the intima to become overstrained, or there may be an underlying tubercle; coughing or any unusual rise in blood pressure or strain upon the pulmonary circulation might cause such a vessel to rupture. In cases of repeated hemorrhages from the lung, nose, ear, and stomach, the patient has been called hysterical until finally the tuberculous focus was discovered.

Tuberculous processes in the bronchial glands may give no warning of their presence and develop insidiously until caseating erosions perforate the trachea or bronchi and cause sudden death. Goodman cites a case of Gerber's:

The patient was a boy, aged six years, who was suddenly attacked with asphyxia and was dead before he reached the hospital. Death was due to the perforation of the anterior wall of the trachea and to the passage through the opening of a piece of cheesy lymph node which blocked the air passage. Gerber assumes that the condition causing death developed insidiously by the cheesy lymph node first infecting and then disintegrating the tracheal wall.

V. Gandiani reported a case of rupture of a caseated lymph node abscess into the trachea:

The patient was a child aged three years, who three days prior to admission, became ill with cough, fever, and respiratory disturbances. The general condition was bad. Diphtheritic serum was administered. The child had a sudden attack of dyspnea, with rapidly progressive cyanosis and symptoms of asphyxiation. Tracheotomy was performed, but the child died half an hour later. At the necropsy the trachea was found to be surrounded by a large packet of lymph nodes as far as the beginning of the bronchi. The anterior wall a few cm. above the bifurcation presented an orifice the size of a lentil. Through the perforation in the trachea a fairly large cavity was reached, which was emptied by pressure from outside, and contained tough, cheesy masses, which also blocked the bronchi. The peribronchial lymph nodes were tuberculous.

Goodman cites eleven cases of sudden death from suffocation from blockage of the trachea or bronchi by caseous masses from perforating lymph nodes; the cases were all alike in the sudden progessive dyspnea. Two of these patients coughed, one paroxysmally like whooping cough; in two cases the diagnosis of diphtheria was made and intubation performed; one case acquired tuberculous meningitis. The onset is usually sudden, often in an otherwise apparently healthy child. Rupture into a bronchus may cause acute pneumonic extensions throughout a whole lobe or a whole lung (Rockhill, 15) or acute miliary pleurisy (Pesch, 16).

Pressure upon the sympathetic may cause irritability of the vasomotors, evidenced by rapid changes from pallor to blushes; unequal or unilateral flushing of the cheeks; a sharply circumscribed patch of color on the cheek; circumscribed reddening in the second intercostal space, associated with menstrual rises in temperature, a consciousness of unstable heart action, of flutterings and palpitations and quickened pulse; unequal pupils and protrusion of the eyeballs (Friedjung, 18).

It is considered probable that a certain class of gastrointestinal disturbances, characterized by lack or suppression of functional activities, may be due to pressure upon the sympathetic nerves, because these disturbances are present in tuberculosis of the bronchial glands when pulmonary tuberculosis cannot be proved and when the syndrome of tuberculous toxemia is not otherwise manifested. This class includes the dry tongue, mouth, and throat; the absolute lack of appetite; the insufficient production of gastric juice; the inacidity; the lack of intestinal secretion; the depression of pancreatic activities and lack of peristalsis; in consequence, there is excessive constipation, nausea, vomiting, and inability to eat. Food is distasteful and repulsive. The symptoms of overexcitability of the vagus system are directly opposite to those of the depressed sympathetic. There is hyperacidity, increased secretion of gastric juice and of bile, increased acidity of the urine, and an unmistakable general acidosis; increased peristalsis means increased frequency of bowel movements; the appetite is keen and may amount to bulimia. In this class of cases pain in the stomach is frequently a very early symptom and may be the first and only one. In Kelling's cases of perforation of the esophagus, the clinical picture was that of gastric ulcer. The fibres of the vagus are very liable to be compressed in erosion of the esophagus by enlarged bronchial glands, and this irritation is felt in the stomach as well as in the larynx; Barety (19) found in his autopsies that twenty-six per cent. had compression or adherence of the vagus fibres. Philippi says that hyperacidity is one of the first signs of tuberculosis. Indigestion is one of the most common causes of an examination. Diaphragmatic pleurisy causes pain in the epigastrium and abdomen, which strikingly corresponds to symptoms found in tuberculosis of the bronchial glands, and which suggests the irritation of the phrenic as a factor in gastralgias. The gastrointestinal disorders common in tuberculosis are probably caused by a combination of influences; irritability of the vagus, the sympathetic, the phrenic, and the effect of toxins; these separate influences can best be recognized by association with their other more specific manifestations. "A very common symptom of occult tuberculosis is pain in the stomach or abdomen, which is not influenced by eating. This pain is characteristic of diaphragmatic pleurisy, but also of tuberculosis of the bronchial glands (20). In both cases it is probably due to irritation of the phrenic by pressure. The pain from diaphragmatic pleurisy is often referred to the appendix, and operations have been performed because of this supposed appendicitis. Lucas (21) reports a case of a child with intercurrent bronchial trouble for over a year. She had lost in weight and had had some digestive trouble at one time, becoming so acute that she was operated on for appendicitis and the appendix was found normal." Many cases of tuberculosis of the bronchial glands show intense nervous dyspepsia, usually with hyperacidity and periodically recurring spasms of pain in the stomach, which may rival the true gastric crises of tabes (Philippi, 17).

It is possible that the rhachialgias and intercostal neuralgias preceding the discovery of tuberculosis of the spine may also be caused by enlarged bronchial glands, and the infection of the spine may prove to be a secondary condition. Rhachialgia is very common in tuberculosis of the bronchial glands; the upper dorsal vertebræ are often sensitive to pressure and are the seat of circumscribed pain; a sensitive spot in the supraspinatus fossa is typically suggestive

of tuberculosis, almost pathognomic; irritation of the phrenic by an inflamed diaphragm is no more specific than its irritation by pressure from enlarged bronchial glands which causes the same pain in the neck, the ridge of the trapezius, the stomach, and appendix. Pain in the region of the trapezius muscle is one of the earliest symptoms of tuberculosis of the bronchial glands (Schlutzkin). So is stiff neck (Hollos, 22). Pains between and under the shoulder blades are very common; they may begin within the chest and radiate to the shoulder or interscapular region (Rockhill, 15) or extend down the arm and be very regularly exaggerated by menstruation (Philippi, 15). Pain over the root of the lung has been specific in many of our cases of tuberculosis of the bronchial glands, with little or no involvement of the lungs. This pain is exaggerated by menstruation and by overstrain of any kind; sewing, writing, physical or nervous strain would make the pain almost intolerable and in two cases prevented usefulness. Patients sometimes are afraid of chilling between the shoulder blades; experience has taught them that chilling of this sensitive spot is invariably followed by "bronchitis." Pain supposed to originate in the lung or pleura or muscles may possibly be a neuralgia, or rather an expression of a neuritis caused by pressure upon a larger branch and felt in its terminal areas. In examining patients, we are often impressed with the circumscribed areas of soreness and pain following the course of the larger bronchi in front and corresponding to their terminal areas. These are typically the second and third interspaces near the sternum; behind the manubrium at the point of bifurcation of the trachea; in the parasternal line from the fourth to the sixth rib, in erosion of the esophagus the fibres of the vagus are likely to be compressed and cause pain behind the manubrium. Just as irritation of the phrenic is felt in the cervical vertebræ, typical pains may follow accurately the insertion of the diaphragm from the sternum to the spine and be associated with a sense of irritation, provoking spasms of coughing seemingly due to pleurisy.

Pressure upon the fibres of the recurrent may cause pain in the larynx, laryngospasm, and paralysis of the vocal chords. Changes in the quality of the voice with a normal larynx and no professional strain upon the voice, is significant and may be a very early manifestation of enlarged bronchial glands. In these cases an examination of the larynx reveals nothing, but too much fatigue of any kind causes changes in the quality of the voice, weakness, hoarseness, or even aphonia, which disappears after sufficient rest, not of the voice only, but general. Physical and nervous or even emotional strain may cause weakness or hoarseness or loss of voice. Persistent pressure may cause symptoms of croup or diphtheria, and coughing varying from a slight clearing of the throat to the violent paroxysms of whooping cough. Barthez and Rillet (23) report cases of periodical hoarseness with a perfectly normal larynx. There was also spasmodic coughing like asthma, coming on usually in the afternoon for little or no apparent reason, but possibly as an expression of fatigue.

TRACHEOBRONCHIAL STENOSIS.

When the tracheobronchial glands enlarge they may form a tumorlike mass extending out across the level of the arch of the aorta, backward over the innominate veins, and upward over the clavicle and into the cervical glands. Under this pressure the trachea and bronchi are not so much constricted as flattened; the wall is thrust in laterally, stenosing the lumen and narrowing it. This tracheobronchial stenosis is much more apt to happen before they have acquired their definite shape and sufficient rigidity; that is, before the third year of life, after which the typical clinical picture changes and becomes complicated by secondary conditions. In the first two years of life the conspicuous consequences of tracheobronchial stenosis are dyspnea and cough. The dyspnea is caused by the difficulty in getting the air out of the lung; inspiration is easy because, as the chest is pulled out, the air passages are widened and the stenosis of the lumina is relieved. As the chest wall falls back and the air passages are compressed, the stenosis returns, the inspired air is imprisoned, expiration is prolonged and difficult. The passage of the air across the point of stenosis is apt to cause a whistling effect, making expiration strident and noisy; if there is sufficient accumulation of fluids in the bronchi and trachea, there may be wet sounds with the expiratory dyspnea, as if a column of fluid were rising and falling or as if the air was passing through it. According to the degree of stenosis, the expiratory dyspnea varies from loud and strident breathing to shrill piping and even whooping. At first the stridor and dyspnea are purely expiratory, but as the glands enlarge and the intima roughens, the air passages become swollen and congested, inspiratory dyspnea is as marked as expiratory. Corresponding to the specific pathological lesion, strident expiratory breathing is the most specific symptom of the bronchial gland tuberculosis of infants. The cough is highly characteristic, but may be confounded with asthma, bronchitis, or whooping cough, which it often closely resembles. The cough associated with whooping, like that heard in expiratory dyspnea, is equally pathognomonic and establishes the diagnosis without even the necessity of seeing the child. As a rule, the cough is very high pitched and resonant, heard at a distance, sharply metallic, and has been compared to the baying of a small hound (Pollak). For a time it may be the first and only symptom, but sooner or later the retention of air causes dyspnea. The cough is most specific when associated with whooping, which, according to Rach, is caused by compression of the main bronchus, usually the right, in the short space between the bifurcation of the trachea and the origin of the bronchus for the right or left upper lobe. After the third year this whooping does not develop. After it is once established it is apt to persist, and later on to resemble attacks of bronchial asthma and capillary bronchitis, which develop secondarily in consequence of the stenosis. Whooping may be induced by moving the child; it may persist during nursing and cease temporarily only during sleep. Variot and Bruder report a case of expiratory strident whooping in an infant six

months old; the thorax was enlarged and hyperresonant on the left side; there was no retraction of the lower intercostal spaces, and no suffocative crises; intubation did not change the noisy stridor; the larynx was normal; there were no adenoids, and the nose was not obstructed; the persistency of the whooping through the tube proved that it must originate in the bronchi, and it was called *cornage respiratoire bronchitique*. The Röntgen ray showed compression of the right main bronchus by enlarged glands. If the child lives and the stenosis persists, the cough changes in accordance with secondary induced conditions. The pressure upon the bronchial vessels causes obstruction, resulting in congestion, irritation, edematous infiltrations, and chronic bronchitis; the bronchial glands become sensitive to any hyperemic agency and acutely irritated in consequence of overexertion of any kind, or from toxins from any source, acute infections, intestinal disorders, etc. These exacerbations are manifested by a tendency to "catch cold," the child always having bronchitis. With care and rest the excessive hyperemia disappears, the voice becomes natural, the child is better, the cough is lower pitched, wet and productive—more like that of chronic bronchitis. The irritability of the bronchial mucosa easily provokes exacerbations and all kinds of bronchitides, so that all chronic bronchitic processes should suggest the possibility of enlarged bronchial glands and the necessity for tuberculin and the Röntgen ray before making the diagnosis. Sanders (24) examined the sputum of persons over sixty years of age who expectorated nights and mornings, and found that tubercle bacilli were present in from 12.5 to 16.7 per cent., although there were no reasons for suspecting tuberculosis, and the diagnosis of chronic bronchitis had been made for years. The mother of one of our patients recently died at the age of seventy-four years, and just before her death the sputum was examined for the first time, and found to contain tubercle bacilli. The diagnosis of chronic bronchitis had been made all during her life. One daughter died of tuberculosis and a son narrowly escaped after a long and dangerous illness.

According to Combe, "the most important sign of tuberculosis in the nursling is the expiratory stertor suggesting asthma. This is an almost certain sign, occurring early and not encountered in other affections in infants. Inspiration is silent, while the expiration is noisy and prolonged, but the infant does not seem to notice it and keeps gay and smiling unless the disturbance becomes too severe and asthmatic." Lees reports a typical case in a child of four years, who had had attacks of asthma ever since it was two years old. There was never complete relief from the dyspnea, but it became worse at times, more especially during the night. The nocturnal attacks were often severe, but one doctor after another stated that there was nothing really the matter, that it was only asthma, because "nothing could be found in the lungs." The boy was thin and wheezed a good deal; the right heart was considerably dilated, and there were areas of dullness over the bronchial glands (25). Vergano (26) reports a case of persistent asthma from earliest childhood, which did not become tuberculous until the age of twenty-six years. It seems probable enough that when a child acquires dyspnea, cough, and asthma, that the fundamental factor may easily be pressure upon the trachea and bronchi, causing retention of air and difficult expiration; this is the typical condition of asthma, but the pathological factor responsible for its production is not always recognized. From asthma to emphysema is but a question of degree; simply a little more intraalveolar distention; simply a little more yielding of alveolar walls and emphysema results. This does not mean that the thorax becomes enlarged or barrel shaped; we have many cases of long, thin thoraxes with hyperresonance and emphysema. "As a consequence of persistent difficulty in expiration, the lung becomes gradually distended and emphysematous, with depression of the base and tympany over the emphysematous areas." (Rach, 7.) "Emphysema in children is usually very serious, because it is nearly always the result of tuberculous processes." (Hayashi, 27.) Years ago Hirtz showed that the so called essential emphysema of the lungs may be the manifestation of tuberculosis. Often it is preceded by asthma, and in neither case does any one suspect tuberculosis, largely because they are commonly supposed to be antagonistic. Hirtz is convinced that the so called chronic bronchitis, asthma, and emphysema may all be the logical consequences of tuberculous processes.

When the backward thrust of the retained air presses too greatly upon the point of stenosis, the bronchial walls may yield and form bronchiectasis, with the characteristic accumulation of purulent sputum not containing tubercle bacilli. When the swollen mucosa and stenosis prevent a sufficient entrance of air to expand the smaller bronchi, they may collapse and form atelectatic areas.

Enlarged glands at the hilum may press upon and impede the return circulation from the lungs, causing stasis, slowing of the blood and lymph currents, and a tendency to sedimentation, making the root of the lung the logical site for the origin of tuberculous processes. When we remember that the alveolar network of bloodvessels covers 150 square metres when fully spread out (Grancher, 28), and that all this immense content must return through the relatively narrow passage of the hilum, it is easily understood how a slight amount of pressure might cause stasis of the circulation in the regions near the hilum, and how these edematous areas favor the accumulation of tubercle bacilli along the peribronchial sheaths. If there is a coincident tracheobronchial stenosis, the tubercle processes will extend into a lung modified by secondary conditions; if the lungs are normal, the peribronchial extensions may remain beyond the reach of physical examinations until the terminal areas of the affected bronchi are involved. When there is no tracheobronchial stenosis and not enough pressure at the root of the lungs to cause edematous rales, peribronchitic infiltrations may advance through the lung without affecting the health or yielding any physical signs until the periphery is reached. According to Jordan, this happens in fifty per cent. of

cases of tuberculosis of the lung. Sclerosed as fast as laid down, they may first be revealed as infiltrations of the apex or irritations of the pleura. A history of a slight sense of irritation just below the larynx and persistent hemming or very slight clearing of the throat too insignificant to notice, combined with attacks of pleurisy and pneumonia, possibly manifested for years or even from childhood, may explain may cases of atypical pneumonias with suddenly fatal endings not in accordance with the mildness of the physical findings which do not suggest such a result. It may be that many of these cases have been susceptible from childhood because of tuberculous processes in the bronchial glands and subpleural, inactive extensions. Very often the history shows lack of strength and vigor, still further confirming the hypothesis. The peribronchial infiltrations may lessen the elastic expansion of the lung and diminish the expansions of the diaphragm.

The consequences of tuberculosis of the bronchial glands may be meningitis; laryngeal disturbances resembling croup, diphtheria, and whooping cough; erosion of the esophagus, trachea, bronchi, and bloodvessels; asphyxiation; hemorrhages; hemoptysis; acute miliary tuberculosis; acute tuberculous pneumonias; chronic bronchitis; asthma; emphysema; bronchiectasis; atelectasis; pleurisy, and tuberculous peribronchial infiltration of the lungs. Von Behring says that the first verse of the song heard over the grave of a victim of tuberculosis was sung over the cradle of a child. Philippi says that the first act in the tragedy of pulmonary tuberculosis takes place in the bronchial glands. Baldwin has stated that natural resistance begins with the earliest infection of childhood.

HIGHLANDS CAMP SANATORIUM.

PYORRHŒA ALVEOLARIS.

By R. G. HUTCHINSON, Jr., D. D. S.,
New York.

It is not my purpose to present an academic dissertation on the theoretical aspect of pyorrhœa alveolaris nor to suggest any experimental line of treatment of a supposititious condition, but I will endeavor to state as clearly as possible the conclusions reached by a careful clinical study of the disease, its causes, and successful treatment. In order to reach a correct conclusion it is necessary, first, to become as familiar as possible with all the conditions attending the disease under consideration, and properly to value the various factors entering into the consideration. Failure to recognize and properly value a single factor results in an erroneous conclusion and makes successful treatment impossible.

Most of the research work which has been conducted relative to pyorrhœa alveolaris has been along the line of bacteriology or a study of systemic resistance to infection. The idea has prevailed that some specific organism is the cause, and numerous efforts have been made to isolate such an organism and to find a successful means of combating it, directly by local application, or indirectly through the blood stream. The local causes of lowered resistance have been almost totally ignored.

This attitude is the result of unsuccessful efforts on the part of those who have conducted local treatment. It has been assumed, and correctly so, that some factor has been overlooked, and that the missing link is either the organism or some systemic disturbance, instead of failure to discover all the local factors and to conduct surgical treatment correctly. Let us consider some of the fundamental principles involved. It is agreed that pyorrhœa alveolaris is the result of infection, but the bacteria causing the infection are practically harmless while normal resistance continues. In order to become effective resistance must be broken down. We have now established two points, namely, that bacteria must be present and resistance overcome.

When we consider that it is impossible to sterilize the mouth, and that even if it could be sterilized it would be impossible to maintain sterility, it naturally follows that the source of infection is the least important factor. Therefore what we must do is to study all the factors which contribute toward lowered resistance at the point of infection. If these factors can be eliminated and prevented from recurring, we need not worry about the form of bacteria, for they are present in every mouth more or less, even where there is no pyorrhea.

I do not mean to say that there is no need of maintaining a sanitary condition, but I refer to organisms which must exist in mouths which are kept scrupulously clean. A systemic disturbance undoubtedly will facilitate the establishment of an oral infection, but unless it is of such a nature that the patient is incapacitated in other respects, it is not an insurmountable obstacle to the restoration of health in the mouth. On the other hand, local injury will sufficiently reduce the resistance of the tissues, so that even when perfect health exists an infection may occur and continue until the cause of injury

has been removed. Health of the tissues depends on cell vitality, cell vitality depends on proper blood supply, and proper blood supply cannot be maintained when there is anything present at a given point which interferes with circulation. These I believe to be the most important fundamental truths for us to bear in mind.

Now let us consider some of the typical forms of pyorrhœa alveolaris. I will take them up in the reverse order of their frequency.

1. An acute suppuration of the gingiva which is the result of lowered systemic resistance, where no local factors exist. These cases are extremely rare and almost invariably come to the attention of the medical practitioner. They respond to treatment of the systemic cause.

2. A general pyorrhea found in very filthy mouths, attacking all the teeth with varying degrees of severity. Such cases will probably be found to predominate in the public clinics and among the class of patients from the poorer sections. This form of pyorrhea is undoubtedly due to the long continued unsanitary condition of the mouth establishing inflammation through the irritating effect of masses of bacteria growing in the food debris and accentuated by the mechanical irritation of the resulting accumulations of calculus. The pyorrhea is not established at once, but is the final outcome when the breaking point has been reached. Establishment of sanitation restores health in such cases.

3. Localized pyorrhea; that is, when only certain of the teeth are affected. These cases are most numerous in the practice of the average dental practitioner. Now if pyorrhea is due merely to the presence of certain organisms or in conjunction with systemic disturbances, why does it attack only some of the sockets and not all?

For many years I have been studying this question and have never of late years failed to find the answer by a careful study of the teeth affected. Invariably the prime factor is trauma, and the most common cause of trauma is malocclusion. So important do I consider it that my first procedure in the treatment of pyorrhea is to relieve by grinding all teeth which are subjected to excessive stress through malocclusion. In most cases it amounts to a complete readjustment of the entire denture. It is worse than useless to perform a surgical operation on tissues which continue under stress. Such treatment would add to the injury, spread the area of infection, and make the formation of new tissue impossible. I believe it is safe to say that not one person in ten thousand has normal occlusion. Instead of the teeth becoming loosened through pyorrhea, in many instances pyorrhea is the result of motion of the tooth in its socket.

Other causes of trauma are crowns, bridges, and fillings impinging on the tissues, incorrect orthodontic treatment, rapid separation of the teeth, injury incident to finishing fillings, impaction of food in interproximal spaces, and in short any mechanical condition which causes inflammation. When the tissue is injured, hyperemia occurs, stasis is established, more or less necrosis of the tissues results, calculus is deposited, and the condition thus established continues until the cause is removed and correct surgical treatment given. Often unskillful treatment itself is productive of trauma, and instead of restored health a worse condition ensues, frequently resulting in a secondary infection more serious than the first.

I have treated many cases of Vincent's angina which were the direct result of such treatment. In order to treat pyorrhœa alveolaris successfully we must be thoroughly familiar with all of the phases exhibited and must recognize the many factors contributing to the condition. Only an extensive clinical experience makes this possible, and the failures of those not possessing such experience or the requisite skill should not prejudice others in their opinions.

It is impossible in the limited space at my disposal and unnecessary for me to give a detailed description of the treatment of pyorrhœa alveolaris. In general it is as follows:

1. Make exhaustive examination of each tooth and surrounding tissue, recording conditions.

2. Correct malocclusion by grinding, and remove faulty crowns, bridges, and teeth which are unfit for retention.

3. At successive sittings remove all calculus and necrotic tissue from crowns and roots of teeth, and trim overhanging fillings.

4. Polish all crowns of teeth perfectly.

Always avoid injury to soft and hard tissues. Lost teeth should subsequently be replaced and faulty dental operations corrected.

No medication is necessary if correct local treatment has been given, and systemic treatment is needed only when other than oral symptoms are present. The common use of emetine and other forms of ipecac during the past year or so justifies me in making special allusion to this subject, and I will quote from my discussion of the subject at a meeting of the First District Dental Society during the past winter:

> No drug will cure a surgical condition. Treatment of pyorrhœa alveolaris by emetine is fundamentally wrong, because we have to deal with conditions which no medication can remove, and the mere destruction of organisms is of minor importance. Of paramount importance is the removal of causes of lowered resistance, both primary and secondary, including the products of inflammation, such as deposits and necrotic tissue. Nothing but skillful surgery, intelligently directed, will do this. It is folly to expect to cure such conditions by the application of any medicament, especially when its sole function is the destruction of a single organism among many which are known to be present and exceedingly harmful to tissue.
>
> In my opinion, it is worse than a waste of time for a man who has definite knowledge of a condition, and ability to treat it successfully, to conduct experiments suggested by some one who evidently does not understand the condition, and who is trying to find a substitute method of treatment which can be successfully employed by those possessing neither knowledge nor ability. We who have made a special study and practice of pyorrhea treatment know this is an impossibility, and we cannot afford to encourage the belief that pyorrhea can be successfully treated by the use of any drug, or without the possession of extensive knowledge of the condition and a high degree of technical skill.
>
> When a patient applies to us for treatment, it is with the belief that we are expert and competent to achieve successful results. We can do this by methods well known to us. Why, then, should we try experiments? As a matter of fact, we have no right to do so under the circumstances. Furthermore, we should not create the impression in the minds of our fellow practitioners that we are groping

in the dark and do not obtain definite results. Those who are competent can successfully treat pyorrhea now, just as competent surgeons can treat other conditions successfully. Those who are incompetent never will be able to do so with or without drugs, and there is no use in their trying.

In conclusion, I would sum up as follows: When there is suppuration without either an unsanitary or traumatic condition, it is reasonable to suppose that the main factor is low general resistance to the organisms present.

When accompanied by an excessively unsanitary condition, we may safely assume that such condition has both overcome resistance and caused the infection.

When the pyorrhea is localized and some cause of trauma exists, why should we look any further for the cause of lowered resistance? How can we expect anything but a pyogenic infection in the presence of the necessary bacteria, contained in an ideal incubator such as the oral cavity?

Think of the result of subjecting a tooth to blows every few minutes or perhaps seconds. These blows varying from a few pounds to perhaps two hundred, concentrated at one point and in a direction unsupported by sufficient tissue. Then add to this a pocket which retains decomposable matter consisting of food débris and dead or dying tissue, deposits of calculus, and an insufficient blood supply. What could be more favorable for the establishment of an infection?

Or suppose that one of those abominations, an ordinary, badly fitted shell crown, is driven down into the soft tissues, producing a painful wound. The gum becomes engorged and swells up around the crown, food accumulates, and eventually after sufficient absorption has been taken to relieve the pressure, it settles down to a chronic state of progressive necrosis.

Is it reasonable in the face of such conditions to expect to find a method of treatment by medication which will restore health? Yet this has often been attempted, and failure has led to the erroneous conclusion that pyorrhea is not simply a local infection.

The correction of mechanical conditions together with delicate surgical treatment and proper sanitation will surely restore and maintain health. I know this because I have accomplished it many hundreds of times.

It is indeed gratifying to have so great an interest shown by the medical profession in the relation between oral infection and systemic disturbances. For years I have dreamed of the time when the medical profession would recognize oral infections as a cause and not an effect of the constitutional disorder, and it seems that the day has come.

We of the dental profession can help you in the treatment of many troublesome cases, and I am thankful that it is so.

Injuries of the Lower Back.—Roland Hammond (*American Journal of Orthopedic Surgery*, August, 1916) reports six cases of severe strain of the lower back, without demonstrable fracture, which were of long duration, marked disability, and which obtained but little improvement, as a rule, under many different methods of treatment.

CHAUFFEUR'S FRACTURE OF THE RADIUS.

By A. C. Burnham, M. D.,
New York.
(*From the records of the Department of Surgery, Vanderbilt Clinic, College of Physicians and Surgeons.*)

During recent years the introduction of the self starter for the gasoline motor has greatly reduced the number of automobile fractures, but especially in commercial lines, the self starter is still somewhat of a luxury, and the fracture is still seen frequently enough to be worthy of study. Moreover, even among the laity, the danger of fracture from the kick back at the starting handle is recognized, the result being that the starting process is approached with due regard to the inherent danger, and this in itself has tended to reduce the number of fractures.

During the last few years the writer has been impressed with the large number of fractures coming under treatment which had been diagnosed as "sprain" and which had in some cases been cared for by physicians for a longer or shorter period as such. Among these were a surprisingly larger number of chauffeur's fracture. Their frequency was great enough to make it plainly apparent that in chauffeur's fracture we are apt to have that peculiar type which shows little or no bony deformity, which may easily be mistaken for a simple sprain of the wrist joint.

Fig. 1.—X ray tracing of the line of fracture in Case I, showing very slight displacement. Styloid of ulnar fractured and slightly displaced.

Fig. 2.—X ray tracing of the line of fracture in Case II, showing slight comminution and displacement backward.

The subject was approached from another viewpoint. Eight consecutive fractures were selected from the clinic records during the previous two years, constituting about twelve per cent. of all fractures about the wrist treated during that period. From the study of these fractures it was seen that bony deformity was the exception rather than the rule, and that the line of fracture did not coincide with what is generally considered as the typical site for Colles's fracture.

We find the earliest references to chauffeur's or automobile fracture about 1899 or 1900, but it was not until 1904, when Lucas-Championnière, in

France, and Madeling, in Germany, described the condition in detail, that the condition became recognized as a clinical entity. During the next few years numerous articles appeared both in Europe and America, and, in 1910, Thomas gave a definite description of the lesion. During recent years, little or nothing has appeared in medical literature, textbooks giving the subject only brief mention.

Fig. 3.—X ray tracing of the line of fracture in Case III, showing high transverse fracture above the epiphyseal line, with slight comminution and displacement backward.

Fig. 4.—X ray tracing of the line of fracture in Case IV, shnwing old fracture with slight impaction.

The earlier writers pointed out that the fracture might be either direct or indirect, the former resulting from the handle of the cranking lever striking the forearm in such a manner as to cause a direct fracture of one of the bones of the forearm at the point of impact. This type is rare and does not differ from other fractures caused by direct violence.

Chauffeur's fractures of the indirect type are most common and are caused by the sudden and violent reversal in the direction of the cranking lever during the manual starting of the motor. It is explained by motor experts that after a gasoline motor has stood idle for a certain period, there is a change in the character of the gas in the cylinders by virtue of which the gas mixture loses its explosive properties. In order to start the motor fresh gas must be forced into the cylinders, and this may be accomplished by turning the engine through one or more revolutions. The motor power may either be the hand or any other force which will accomplish the same result. If the explosion is timed to occur before the piston reaches the highest point in the cylinder, that is, if the spark is advanced, the piston will be forced backward, causing a reversal in the direction of the starting handle which is usually transmitted to the palm of the hand which grasps the lever in the shape of a sudden and violent blow.

This force may act upon the radius in two ways; either by means of impaction transmitted through the palm in the region of the thenar and hypothenar eminences, or by means of hyperextension of the hand, which is transmitted to the radius through the strong anterior ligaments of the wrist joint. Theoretically, the cases due to impaction would show fractures identical with or approaching the lesions of Colles's fracture, while hyperextension would cause lesions with more of the characteristics of the so called sprain fractures of the lower end of the radius.

If a study is now made of a series of x rays of chauffeur's fracture, it is seen that in very few of them is the lesion that of the typical Colles's. In fact, in the present series of eight consecutive cases, no single one of them could be described as a typical Colles's fracture. The mechanics of Colles's fracture, according to Stimson,[1] is that of a force which acts either by splitting or crushing of the radius between the carpus and the diaphysis, or an action due to decomposition of force from a blow on the palm in a direction slightly inclined from the long axis of the radius. Fracture may result from hyperextension, but experiments upon the cadaver have shown that such fractures are usually low transverse fractures and not associated with posterior displacement and silver fork deformity.

Now this experimental fracture in the cadaver is of exactly the same type as that seen in chauffeurs. In only one case in the present series was the line of fracture as high as that seen in Colles's fracture. This case (Fig. 3) occurred in a youth eighteen years old before the fusion of the epiphysis and diaphysis, and showed very little displacement and slight silver fork deformity. The remaining cases without exception showed fractures running near or into the lower articular surface with little or no deformity. In only two cases was there any evidence of a tendency to impaction (Figs. 2 and 4) and in these cases the impaction was very slight. Displacement was absent in some cases, in others there was a slight amount of rotation backward of the lower portion through the long axis of the fragment. These fractures correspond almost exactly to the type of experimental fracture in the cadaver and probably are frequently due to hyperextension.

Fig. 5.—X ray tracing of the line of fracture in Case V, showing fracture similar to Case I, but passing entirely across the bone, without impaction or displacement.

Fig. 6.—X ray tracing of the line of fracture in Case VI, showing fracture practically identical with Case V.

The symptoms vary according to the lesion. Personally I have come to look upon the slightly oblique fracture, which passes into the joint (Fig. 1), as the

[1] Stimson: *Fractures and Dislocations*, New York, 1912.

most typical form of chauffeur's fracture, and this was seen in two cases in the present series (I and VIII). Three other cases (Figs. 5, 6, and 7) are nearly identical with Case I, but in these the fracture can be made out to pass entirely across the carpal extremity of the bone, reaching the ulnar margin of the radius at the junction of the carpal and ulnar articular surfaces. In most of these cases (I, V, VI, VII, and VIII) there is little or no bony deformity and false point of motion is obtained only with great difficulty.

The patient presents himself with only a moderate loss of function and very little pain. Indeed, some chauffeurs are able to drive their cars for several hours after the injury has occurred. One patient drove his car for ten days after the injury and presented himself at the clinic only because of his inability to crank the motor. The wrist is usually swollen and shows areas of ecchymosis, and the physician is called upon to exercise considerable ingenuity to differentiate the injury from simple strain.

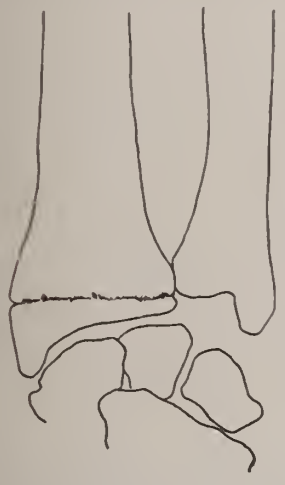

Fig. 7.—X ray tracing of the line of fracture in Case VII, also similar to Cases V and VI.

If we remember that a wrist sprained severely enough to cause the patient to seek medical advice is very rare, and if we also remember that this fracture may occur without deformity, the diagnosis becomes comparatively simple.

Given the history of the case, there is only one additional symptom necessary for the diagnosis, and this is the typical localized tenderness over the line of fracture. This has been called "wincing" tenderness, and is easily obtained by direct pressure over the line of fracture. It is most marked upon the second and third days and persists until the third week or even longer. If this line is carefully marked out with a blunt instrument, it will be found most commonly to run close to the articular margin,[2] and the tenderness will be found both on the palmar and dorsal aspects of the wrist; whereas, in sprain from the same cause, the tenderness is most marked interiorly.

There is usually no change in the relation of the styloids, although in about twenty-five per cent. of the cases reported the ulnar styloid has been fractured and sometimes displaced. Certainly any upward displacement of the tip of the radius is very rare.

It need hardly be stated that in this border line type of fractures a skiagram is especially advisable. The line of fracture is often indistinct, and unless the plate is so taken that all finer details are brought out, the lesion may easily be overlooked.

TREATMENT.

The treatment of chauffeur's fracture does not differ from that of the ordinary fractures about the wrist in any essential detail. Naturally cases showing linear fracture without displacement do not require reduction. The wrist may be put up in slight flexion to overcome the tendency to backward tilting of the lower fragment. In the exceptional cases with considerable displacement, the fracture should be reduced and the condition dealt with in the same manner as Colles's fracture.

The milder cases should receive early massage and passive motion and rarely require fixation longer than three weeks. In these cases a posterior moulded plaster splint has been found most satisfactory, the splint extending from the metacarpophalangical joint to a point just below the head of the radius. This permits limited use of the hand, the patient being allowed light work after the tenth or twelfth day.

When untreated, chauffeur's fracture sometimes results in permanent stiffness of the fingers and wrist joint, but early recognition of its presence followed by appropriate treatment is practically always attended by good results.

CASE HISTORIES.

Case I (Fig. 1). Fracture in man of twenty-one years, linear, oblique, showing very slight displacement. Styloid of ulnar fractured and slightly displaced. Treated as sprained wrist for ten days—not reduced. Functional results excellent.

Case II (Fig. 2). Male, aged twenty-six years. Showing slight evidences of comminution. Very slight displacement backward. Treated as sprain. Anatomical and functional results satisfactory.

Case III (Fig. 3). Male, eighteen years. Showing high transverse fracture above epiphyseal line. No impaction. Slight comminution. Slight displacement backward. Reduction easy. Results excellent.

Case IV (Fig. 4). Male, forty-eight years. Injured wrist four weeks before. Old fracture showing very slight impaction. Reduction not attempted. Massage and passive motion for three weeks. Functional result good. Anatomical result fair.

Case V (Fig. 5). Male, twenty-eight years. Line of fracture similar to Fig. 1, but passing entirely across the bone. No impaction or displacement. Did not return for treatment.

Case VI (Fig. 6). Male, thirty-five years. Lesion practically identical with Case V. Treated as sprain for four days. Stopped treatment after two weeks.

Case VII (Fig. 7). Male, thirty-one years; came into the clinic within one half hour of the accident. At that time the slight irregularity along the anterior margin of the lower end of the bone could be distinctly palpated as a sharp spicule of bone. Dorsally, nothing could be felt. Reduction was considered unnecessary. X ray showed line of fracture similar to Case V. Results excellent after three weeks.

Case VIII. Male, twenty-seven years. Line of fracture same as Case I. No displacement. Reduction unnecessary. Excellent results after four weeks.

140 West Seventy-ninth Street.

[2]The x ray tracings are made to show this line clearly. In the original negatives the line of fracture was frequently very faint.

PSEUDOSCARLATINA.

By Bernard Frankel, M. D.,
New York.

For several years past I have observed among children—usually during the prevalence of influenza—numerous cases which, although resembling scarlet fever, differ from it essentially, and etiologically seem to be more closely related to influenza. They possess, however, a clinical entity of their own and, because of their resemblance to scarlet fever, I

thought it most appropriate to designate them as cases of pseudoscarlatina.

A previous attack of true or pseudoscarlatina does not confer immunity against a new attack of the latter. The onset as in true scarlet fever is usually sudden, with elevation of temperature and a scarlatiniform rash, both however less pronounced; and the subsequent course is as a rule milder than that of true scarlet fever, the temperature being lower—although subject to irregular exacerbations—and the rash paler, more evanescent, and followed by more minute desquamation.

The two forms differ greatly as to complications. I have never observed acute nephritis complicating pseudoscarlatina, but more frequently than in true scarlet fever do its complications involve the throat, ears, the respiratory and digestive tracts, while a cervical adenitis is almost invariably present.

The angina ranges all the way from a very mild tonsillitis to a severe and even fatal septic sore throat; purulent otitis media at times occurs; while the respiratory tract involvement, usually beginning with a more or less severe rhinitis, may not pass beyond an acute bronchitis in the mild cases or eventuate in a more or less severe attack of bronchopneumonia in those of a severer type.

In a similar manner the gastrointestinal disturbances may manifest themselves only by anorexia, nausea, vomiting, and irregularity of the bowels in the milder cases; may take the form of a more or less severe acute enterocolitis—usually accompanied by enlargement of the spleen—in the severer ones; or may even, in the very severe cases, show symptoms closely resembling typhoid fever.

The prognosis is very good in mild cases, but in the severe ones often doubtful; recovery is tedious, interrupted by severe relapses, and followed by prolonged impairment of the general health.

The following interesting case, although not at all characteristic of the ordinary mild cases, may serve as a good illustration of some of the complications of the severe cases of pseudoscarlatina.

Case. In December, 1909, I was called to treat Levy, six years old, of Market Street, New York. The boy awoke that morning with a typical bright scarlet rash all over his body, his temperature at 10.30 a. m. was 103.5° F., his pulse 140, and respirations were 35. His throat was congested and the cervical glands were enlarged. It looked like a typical case of scarlet fever.

Within twenty-four hours the rash completely disappeared and the temperature, pulse, and respirations dropped almost to normal; but twelve hours later, at about 10 p. m., the temperature was again up to 103° F. and he began to cough. Physical examination disclosed medium sized moist rales over his right upper lobe posteriorly, but no dullness on percussion, except over his left lower lobe posteriorly, due to enlargement of the spleen. His bowels became loose, the stools small, with some mucus, and accompanied by tenesmus.

During the following three days the temperature, pulse, and respirations continued high, with at times slight morning remissions and irregular exacerbations; the respiratory symptoms remained about the same. Diarrhea was controlled by soothing and astringent enemata, but the spleen was now readily palpable below the costal arch, the abdomen much distended, and the tongue furred and heavily coated, not unlike the tongue of typhoid. The Widal test was negative.

Dr. Emmet Holt was kind enough to see the case with me then and fully confirmed my diagnosis of influenza, complicated by severe abdominal symptoms and by an impending bronchopneumonia. He also agreed with me that many of the symptoms made it necessary to eliminate typhoid, and that the treatment should continue to be sustaining and stimulant, avoiding expectorants likely to irritate the stomach.

Within the next few days bronchopneumonia did develop, but was soon resolved, the temperature came down by lysis, and the patient entered the stage of a slow convalescence with three or four lapses.

In other cases a more or less severe and sometimes even fatal septic angina is a frequent complication.

I am certain that many a busy practitioner, on looking over the records of his scarlet fever cases, will find that a good many of the mild recurring cases, as well as of the graver ones, accompanied by severe, possibly septic anginas, were in reality cases of pseudoscarlatina, although in a routine way pronounced even by the diagnosticians of the board of health to be cases of true scarlet fever.

It is the purpose of this communication, by endeavoring to put these cases in a class by themselves and to dissociate them from true scarlet fever, to focus upon them the attention of physicians endowed with better equipment and facilities for the necessary thorough study and research work. Bacteriological examinations especially will have to be carefully followed up.

Abstracts and Reviews

THE NEW PHYSIOLOGY.*

By Professor J. S. Haldane,
University of Oxford.

The lecturer opened with a brief review of the conceptions and principles which have guided physiological thought and investigation in the past. He pointed out that the original conceptions were dominated by the attitude of vitalism and that under this influence the observed phenomena which could not otherwise be explained were ascribed to vital action. Then, with the great advances which were made in chemistry and physics, and more especially in the field of biochemistry, a new orthodox creed sprang up and has persisted to the present day. This creed sought to explain all physiological phenomena in the terms of physics and chemistry and would make biology a mere branch of these two sciences. Such a creed would postulate a finality of knowledge in the domains of physics and chemistry, but it has become evident that our knowledge in these two branches is far from final and complete, and we are now struggling to go beyond the molecule and the atom and study electrical phenomena and those of radioactivity among others. On the physicochemical basis the physiological investigators sought the ultimate causes of the several phenomena of living tissue, but it soon became evident that neither chemistry nor physics was adequate to reveal and explain the ultimate causes.

*Summary of a lecture delivered before the Harvey Society at the Academy of Medicine, New York, October 14, 1916.

This mechanistic, or physicochemical doctrine, failed to recognize the fact that physiological response in living cells depended upon the maintenance of normal conditions of life in the cell.

According to Professor Haldane's view, therefore, the failure of both the vitalistic and the mechanistic doctrines necessitated new methods of approach if physiological advances were to continue. This was the the basis of the new physiology, as he termed it. The new physiology recognized that biological phenomena or physiological responses of living cells depended primarily upon the maintenance of the normal in the cell. The maintenance of the normal, in turn, rested upon a vast number of variable factors which interacted one with another in a multitude of different ways. It was then to be the duty of physiology to study the individual factors and their interactions—to trace out the normal phenomena of activity of living matter—rather than to seek their causes.

To illustrate the methods of this new conception, the speaker chose the physiology of respiration as the subject with which he was most familiar. Observation showed that normal breathing was irregular and was altered by extremely slight influences. Thus the mere effort of talking or laughing, slight exercise, and a host of other factors altered its rate, depth, and rhythm. The view commonly obtained that the depth of normal breathing could be increased by athletic training; and it was known that a period of excessive ventilation was followed by one of apnea. The breathing of an excess of carbon dioxide was known to increase respiratory ventilation, but this increase was not in direct ratio to the concentration of the carbon dioxide breathed. The apnea produced by superventilation was originally held to be due to cumulative vagus influences acting upon the respiratory centre, for the vagus was known to transmit stimulant and inhibitory influences to and from the centre. It was soon found that the alveolar air contained a constant percentage of carbon dioxide under normal conditions. Changes in rate or in depth of breathing were normally compensated by alterations in the other, so that the concentration of carbon dioxide in the alveolar air always remained the same. Pursuing these observations further, it was shown that the apnea of superventilation was due to the removal of a slight excess of carbon dioxide above the normal. Thus a lowering of the carbon dioxide by as little as 0.2 per cent. caused apnea. On the other hand, raising the carbon dioxide by an equal amount produced hyperpnea. The regulation of respiration was thus proved to be chemical, and the sole functions of the vagi in this connection were to aid in the coordination of the respiratory acts and to prevent unnecessary waste of time. There was no such thing as vagus apnea—apnea was solely of chemical origin and depended upon the excessive removal of carbon dioxide from the blood.

Proceeding further along these lines of investigation of normal phenomena, it was found that the carbon dioxide acted by virtue of its acid property. The introduction of new and extremely delicate electrical methods of measuring the reaction of the blood in terms of the hydrogen ion concentration, paved the way for the further study of the phenomena of respiration. It was soon proved that the hydrogen ion concentration of the blood was maintained at a constant level in spite of very great external changes. This constant was found to be dependent upon the maintenance of a balance between the alkali salts and the albuminoids of the blood. It was then but a step to show that the respiratory centre reacted to the hydrogen ion concentration and that an extremely delicate balance was maintained between the concentration of carbon dioxide in the blood and the alkali salts and albuminoids. Disturbances in this delicate balance were at once reflected in the respiration which was altered in rate and depth so as to increase or diminish the excretion of carbon dioxide. The state of the alkali albuminoid balance, in turn, regulated the carbon dioxide carrying power of the blood.

The net result of these investigations had been to show the existence of four normals or constants concerned with the regulation of respiration. These were: 1. The partial pressure of carbon dioxide in the alveolar air; 2, the regulation of the hydrogen ion concentration in the blood; 3, the response of the respiratory centre to the hydrogen ion concentration; 4, the regulation of the blood's carrying capacity of carbon dioxide.

After elaborating the principles of the new physiology by this brief outline of the understanding of the respiratory mechanism which they had given us, the speaker proceeded to indicate that the same methods could be applied to the other branches of physiological study. Thus it was pointed out that the composition of the blood in a similar manner was physiologically regulated in all its details. In the normal state the concentration of sugar remained constant within extremely narrow limits, and such extreme artificial variations as prolonged fasting and excessive intake of sugar did not alter the concentration of this substance in the blood. The same was true of sodium chloride and other salts and the author and his associates had recently attempted to measure the changes produced in the blood dilution as the result of the ingestion of very large amounts of water. They found that when water was taken very freely the kidneys responded with great diuresis, but the fluid excreted by them under such circumstances was little more than pure water. Even after extreme amounts of water were taken the blood serum showed only very slight diminution in its salt concentration when tested by delicate methods for determining its electrical conductivity.

It was pointed out, in further illustration, that it was hopeless to attempt to explain the functions of the kidneys on the ordinary grounds of physics and chemistry. Even the subject of nutrition had to be approached from the standpoint of the new physiology rather than from that of chemistry, as it was already evident that there was a delicately maintained balance of energy values through the substitution of one type of food for another.

The speaker emphasized that this new physiology was not a return to the creed of vitalism, but was pure biology. Its sole purpose was to seek out and recognize the phenomena which maintained the uni-

fied normal in living matter. It must recognize that each individual phenomenon was closely related to many others and that each was merely a part of the whole. The duty of the new physiology was to investigate the details of the parts of the whole and thus to add to our knowledge of the whole. Structure and action were manifestations of life, not physical and chemical phenomena merely. Protoplasm was everywhere in active relation with its environment, and the internal structure of cells and tissues depended upon the constancy of the composition of the blood. The converse was equally true —that the constancy of the composition of the blood depended upon the actions and structures of the cells and tissues. In the living organism, however, there was a very elastic state of adaptation for the maintenance of the normal. Investigation along the lines of the new physiology showed the existence of normals and their interrelations, but these could not be analyzed in the terms of the mechanistic theory on physical and chemical bases.

Such a new physiology bore directly upon medicine, for the latter had for its object the maintenance of health, and health was synonymous with normality. It behooved the physician to have a clear conception of the normal, so that he might interpret correctly the deviations from it, and much was to be gained if the tenets of the new physiology were applied to the study of pathology and pharmacology. Pathology should seek to discover the processes of defense and adaptation and the methods by which the organism tended to be restored to normal. Pharmacology should seek to discover how the normal might be restored through the help of drugs.

Contemporary Comment

Fraudulent Infantile Paralysis Cures.—The U. S. Department of Agriculture has instructed Food and Drug Inspectors to watch all interstate and foreign shipments for fraudulent remedies advertised to cure infantile paralysis, as it is expected that the present epidemic will tempt unscrupulous persons to offer for sale so called cures or remedies for this dread malady. The inspectors, as stated by the *Saint Paul Medical Journal* for September, 1916, have been ordered to warn the public that any preparation put on the market or offered for sale as being effective in the treatment of infantile paralysis should be looked upon with extreme suspicion. Samples of all such medicines will be collected and investigated by the Department of Agriculture. Makers of such fraudulent remedies will be vigorously prosecuted wherever the evidence warrants action under the Sherley Amendment to the Food and Drugs Act. So called remedies for infantile paralysis which are offered for import to this country will be denied entry. Already inspectors have discovered shipments of a few such mixtures. The Department of Agriculture will do everything it can under Federal law to protect that portion of the public which is extremely credulous in times of panic and which grasps at anything which promises protection or relief. The sale of such products at this time is pointed out to be particularly threatening to the public health because many persons, relying on the false statements of impostors, neglect to secure competent medical advice and as a result not only is the safety of the patient endangered, but in the absence of proper sanitary precautions the likelihood of contagion is greatly increased. It is to be understood that the Federal Food and Drugs Act applies only to products which are shipped in interstate commerce, that is, from one State to another, or which are offered for import or export, or which are manufactured or sold within a Territory or the District of Columbia. Products which are made and consumed wholly within a single State are subject only to such State laws as may apply and are under the control only of State health officials. Persons buying or using a remedy made in their own State, therefore, must rely on the protection accorded them by their local health authorities.

Qualifying for the Practice of Medicine.—The Christian scientists are making a great ado about the effort on the part of members of one of our district medical societies to obtain information from legislative candidates concerning the attitude to be assumed by them in connection with requirements for the practice of medicine in the State of Indiana. Printed circulars are sent forth from Indianapolis with the reproduction of the letter sent out by the secretary of the medical society, and a reproduction of some rather sarcastic comments by a Kokomo newspaper that has a reputation of being a little lopsided on many questions that demand nothing more than a little common sense to settle satisfactorily. As a matter of fact, asserts the *Journal of the Indiana State Medical Association* for September 15, 1916, all that the medical profession has asked of candidates for the legislature is that they shall establish a standard of fitness for the practice of medicine, just as a standard of fitness is established for many other things. If a man is going to treat the human body, he ought to know something about the human body, and he cannot obtain this knowledge by reading Mrs. Eddy's *Science and Health; a Key to the Scriptures,* nor can he obtain such knowledge through a six weeks' course of massage training in a chiropractic school. Nothing more is asked than that the person who is licensed to practise medicine must have a suitable preliminary education, and that he shall have studied medicine and the allied branches relating thereto a sufficient length of time to make him acquainted with fundamental facts. When he has done this, he will have shown some fitness for the practice of medicine, and common sense as well as the protection of the people indicates that this method of securing competence is fair and just. As the medical men say in their letter sent out to candidates for legislature, "No exemptions should be made, and no discriminations permitted, and all should be measured with the same stick." We hope that the medical men of Indiana will make their influence felt among those who are candidates for the legislature, for the surest way to accomplish results is through the medium of politics.

NEW YORK, SATURDAY, OCTOBER 21, 1916.

THE ENGLISH PHYSICIANS' SUBSTITUTE FOR GASOLINE.

One of the scarcities due to the war most keenly felt by our professional brethren in England is the dearth of gasoline. Practically all of that commodity used by England is imported, and the troubled state of the waters around that tight little island has caused many American shippers to fear lest their oil should be thrown on them by the forcible persuasion of a torpedo. The vast amount required by the expeditionary forces and the diversion of English ships formerly used for gasoline to other purposes have had their effect. Early in the spring of 1916 the Board of Trade appointed a committee to control the supply of gasoline and this body immediately put restrictions into effect which have grown more and more rigid.

This Petrol Committee has had the good judgment to favor the medical profession as far as possible so that physicians are allowed as much as they ask for up to a maximum of fifty gallons a month. This has been found insufficient, however, in some cases; the war has caused a shortage of physicians with a resulting increase in the work of those remaining. Leaking and wasteful engines, accidents, delay in filling requisitions, and many other things may cause physicians to run short of gasoline before their allotted time is up, so they have sought a solution of the problem in one of two ways, either a substitute for gasoline, or more miles to the gallon.

Many things have been suggested to replace gasoline either wholly or in part. Alcohol has been mentioned, but the supply is just as restricted if not more so than that of gasoline, although in the course of time the production of this fuel might be brought equal with the English demand, which could never be the case with oil. Benzole has been suggested, but at present there is a greater need for coaltar products either by the government or in the dye industry.

The most practical substitute which has been suggested is paraffin oil, a heavier grade distillate of petroleum than gasoline. To use paraffin oil alone as a fuel would mean the employment of a different carburetor, and whether or not the profession would be justified in going to the expense of such a change when the supply of paraffin oil is just as uncertain as that of gasoline, is debatable. A method which has been found by many practitioners to work well is to mix a small quantity of paraffin oil with the gasoline, in the proportion, say, of one to ten at first and then gradually to increase the proportion of paraffin oil, as long as the carburetors can take care of it. Of course two fuel carburetors can be obtained; the chief point of interest to the medical man is the problem of quick starting, especially in cold weather. The method which seems to have given the best results in practice is a two fuel carburetor by which the car can be started on gasoline and then switched to paraffin oil.

Many arguments can be adduced for and against the use of paraffin oil. What seems chiefly to exercise the minds of the British profession is the fear that even should they find an alternate fuel which is satisfactory and adjust their machines to use it, this too would soon be unable to fill the increased demand. Such a contingency is hardly likely to arise here if the United States should become involved in war, as our supply of crude oil is ample, but perhaps some ingenious Yankee can make a suggestion which will relieve our British cousins.

PENETRATING WOUNDS OF THE LUNG AND PLEURA.

At one time penetrating wounds of the chest were almost invariably fatal, or at least the mortality rate was exceedingly high. L. A. Lagarde, U. S. A., in his work on gunshot wounds, published in 1914, showed that the mortality of penetrating wounds of the chest in the French army during the

Crimean War was 91.6 per cent., in the British army over seventy per cent., and among those who survived to reach hospital in the American Civil War, it was sixty-two per cent.

With the introduction of small bullets of high velocity, however, it began to fall and the fall seems to have been progressive. For instance, in the Spanish-American War, it was 27.5 per cent.; in the Boer War fourteen per cent., and among the Japanese in the Mukden battle 3.67 per cent. Some fallacies have doubtless crept into the foregoing figures. Such extremes are very difficult to understand, for while the Japanese are, perhaps, a hardier race than either the Americans or British, and while their sanitary arrangements may have been more strictly enforced than in either of the other armies, the difference in the mortality rate is too great not to be regarded with distrust. Yet it is certain that the death rate from penetrating wounds of the lung and pleura are less deadly by far than was formerly the case. Indeed, unless a wound of this nature is quickly fatal, the prognosis is favorable. Dr. Hale White, in the *Lancet* for December 4, 1915, states that among the many cases in hospital since the outbreak of the war, he has not witnessed a single fatal one. The reason he gives is that the bad cases never reach England. Many victims are killed on the spot, some get no further than the field ambulance and casualty clearing hospitals, while others again succumb to their injuries in the base hospitals of France. Only those who are practically out of danger reach England.

In the *Quarterly Journal of Medicine* for July, 1916, Dr. R. D. Rudolf narrates his experience of treating gunshot wounds of the chest received in the battle zone, and points out that one of the first things that strikes the attending medical men is that apparently hopeless wounds, judging from their anatomical position in the chest, may give rise not only to no dangerous symptoms, but almost to no discomfort. That is, a bullet may pass clean through the lung without producing any lesion that can be detected by physical or x ray examination. Usually, however, there is at least some hemoptysis. Writing in the issue of this Journal for September 30th last, R. Murray Leslie points out that effects of penetrating wounds of the chest depend upon two factors: 1. The direction and site of the bullet track; and, 2, the presence of septic material within the thoracic cavity. Thus wounds in the middle of the chest or central zone are extremely dangerous. Wounds of the peripheral or lateral zone involve least risk, and wounds in the middle zone are more serious. Lateral, transverse wounds are much less dangerous than we should imagine, and as Leslie says, it is extraordinary with the modern small, high velocity bullet, how often the important structures in the posterior mediastinum escape injury.

No statistics have been given so far with regard to gunshot wounds in the French or British armies, but it seems more or less certain that the fatalities will be higher than in the Boer or Russo-Japanese War. Shell fragments and shrapnel wounds are more likely, by far, to carry in infected material from the skin and clothing than the small pointed high velocity rifle bullets. On the western front the war has chiefly been one of big artillery, firing explosive and shrapnel shells, and machine guns, while the high velocity rifle bullets which were the main causes of injury in the Boer and Russo-Japanese war, have not been much in evidence. Consequently, the wounds have been more greatly lacerated, tending to facilitate infection. A curious point with regard to infection of chest wounds is that although the entrance and exit wounds are generally septic, the bullet track in the lung appears, as a rule, to be sterile.

THE IMPAIRMENT OF HEARING BY EXPLOSIONS.

Wicart addressed the Académie de médecine on this subject on September 15, 1916 (*Presse médicale*, September 21st), stating that the damage done to the hearing by violent and long continued explosions on the battlefield could be minimized by a little care. The soldier should: 1. At the moment of the discharge or an instant later, forcibly swallow the saliva three or four times in succession, at the same time compressing the nostrils together. 2. During bombardments the external ear should be filled with cotton wick soaked in glycerin, and the ears and mastoid region covered with ear muffs of carded cotton. These precautions were simple but efficacious. When the men were taken by surprise and had not time to carry out these suggestions, they need not fear infection unless they were already suffering from mucopurulent nasal or pharyngeal catarrh, hypertrophied or atrophied turbinates, deviated septum, old cicatricial otitides, hardened wax in the ear, cephalic congestion following syphilis, malaria, rheumatism, or alcoholism.

The men in the trenches and those in the artillery should perform a daily toilet of the ear and nose by filling the former with glycerin and the nose and pharynx with camphorated oil, with essence of lavender or eucalyptus added, one in 100. Mentholated petrolatum has been used, but is distinctly inferior. The instillation should be made with the subject lying supine, his head thrown back for five minutes subsequently. Even if explosions have taken place these instillations should be made, be-

cause, if neglected, a suppurative otitis may be set up, although the drum membrane may not have been ruptured.

NEGLECT OF OPPORTUNITY.

Some ten years ago the up to date dean of one of our up to date medical colleges, in an address to the alumni of the school preparatory to a drive for a larger and more useful institution, made a special point of the need for better teaching and more thorough clinical application of the mechanical means of treatment of disease. The years have passed and there is no more instruction given in this school in either the theory or practice of such therapeutic measures, nor is there a more extensive use of these means in the hospital controlled by this college. Though this school has increased its facilities for doing work that "meets the requirements" of the powers that set the pace in medical education, it is significant that these requirements themselves do not include any department or any teachers of this very important branch of medical practice.

Progress in science consists in periods of quickening along certain lines that have become popular followed by periods of paralysis, or at least of strange inertia and neglect in those directions. Medical science has, in the past, made much of massage and other mechanical means of cure, but at present chemistry seems to have quite ousted any very serious thought of physics in therapeutics. The value of the horizontal position for the seriously sick has held its own, the Trendelenberg and Fowler's positions are considered useful, but active physical measures are well nigh ignored. This neglect has been taken advantage of, in fact has led to the very existence of a host of healers with high sounding titles who reap a harvest of shekels and who in doing so must, by inference, help their patients in some degree, and also give rise to the suspicion that the medical profession does not know its business as well as it might.

It is very well to say that those who are benefited by the simple methods of these sects, whose theory is nonsense and whose practice is usually unskilled, are not sick but simply need muscular exercise—passive if no other. A man or woman who needs exercise is sick as well as one who needs hydrochloric acid or morphine, and it is just this sort of people who make up the majority of the clientele of every physician who has to treat other than the poor.

It is not only these indolent, ambulant patients who benefit by and fairly demand mechanical treatment. The bedfast sick are often helped to recovery by judicious massage and passive movements, while the repair of injured joints and bones is wonderfully facilitated by such help. The time saved in convalescence and the more perfect outcome in function has made thorough thermal and mechanical treatment after injuries a most important matter in European countries, and during the present war it has been brought to even greater perfection.

Physical means of treatment, especially massage, has in times past fallen into disrepute because of its abuse by those who practised it, and no doubt its present neglect by the profession is due, in large part, to a desire to shun apparent association with those who, in the absurdity of their theory and the indiscriminateness of their practice, savor strongly of the charlatan. It would be better, however, to defeat these people with their own weapons used conscientiously than to ignore the good in their methods. At any rate our institutions of medical teaching should give full theoretical and clinical presentation of all physical methods which can be applied with advantage in the cure of disease.

SYPHILIS AND WORKMEN'S COMPENSATION.

A workman was injured by an accident in a sawmill at Traverse City, Mich. Under the workmen's compensation law payments were made for a period of nineteen weeks, when the employer refused to make further payments, upon the ground that the employee's continued disability was due to syphilis, which retarded the healing of the wound.

The Michigan Supreme Court decided that payments must be continued. Justice Person in the opinion said: "The consequences of the injury extend through the entire period, and so long as the incapacity of the employee for work results from the injury, it comes within the statute, even when prolonged by preexisting disease."

The opinion is published in the issue of *Public Health Reports* for September 29, 1916, page 2725.

ALCOHOL IN THE TROPICS.

F. Lucas Benham writes a spirited letter on this subject to the *Lancet* for September 23, 1916. "In a review of Woodruff's *Medical Ethnology* in the *Lancet* for June 10, 1916, p. 1172," he states, "your reviewer speaks of the author's 'surprising conclusion that those who drink alcohol in the tropics enjoy better health than abstainers.' I cannot see anything surprising in this. I should rather be surprised if the contrary were maintained. It is, as in other climates, a matter of *quale, quantum,* and *quando*. I should have thought that there was plenty of evidence in print of the wholesomeness of alcoholic beverages everywhere. To give a single instance of an active, hard working man in tropical Africa, let me refer your reviewer to Sutherland's *Adventures of an Elephant Hunter,* p. 169. I think that he will admit that there are, at any rate, exceptions to his own views. Nowadays,

when there is so much bigoted antagonism to the use of alcoholic drinks, and it is often looked upon as a virtue to abstain, it is as well to take broader views and recognize the beneficence of their action, and to encourage the moderate and judicious use of them. What would the British nation have been without beer and wine, and what would it sink to if it gave them up entirely?"

News Items

Rush Society Lectures.—The first lecture in the series for this year was given in Thomson Hall, College of Physicians, Philadelphia, Thursday evening, October 19th, by Dr. John Scott Haldane, of Oxford University, his subject being the New Physiology.

The Medical Club of Philadelphia held a reception on Friday evening, October 20th, at the Bellevue-Stratford Hotel, in honor of the following past presidents of the club: Dr. Hobart Amory Hare, Dr. James M. Anders, Dr. Edward E. Montgomery, Dr. L. Webster Fox, Dr. S. Lewis Ziegler, Dr. James C. Wilson, Dr. Samuel D. Risley, and Dr. McCluney Radcliffe.

Masonic Hospital at Elizabethtown, Pa.—Free Masons of Philadelphia have presented to Elizabethtown a hospital thoroughly modern in all its appointments. The building is of Gothic design, is built of granite with limestone trimming, and cost $60,000. This is the first of three buildings which the Philadelphia Free Masons are to give to Elizabethtown, the others to be connected with the hospital by corridors.

Surgical Experience in a Base Hospital.—At a meeting of the Northern Medical Association of Philadelphia, to be held on Friday evening, October 27th, Dr. Hermann Fischer, of New York, will deliver an address on Six Months' Surgical Experience in a German Base Hospital. The profession in general is invited to attend, and all physicians who have had experience in base hospital work are invited to discuss the subject.

Philadelphia Hospital to Be Rebuilt on Present Site.—Members of the medical board of the Philadelphia Hospital met on Monday, October 16th, and unanimously approved the plan of rebuilding the hospital on the present site at Thirty-fourth and Spruce Streets, instead of establishing a district hospital as had been suggested. There is now $1,000,000 available for expenditure on the hospital, and plans have been drawn for one large building.

State Medical Society of Wisconsin.—At the annual meeting of this society, held in Madison on October 4th and 5th, Dr. H. E. Dearholt, of Milwaukee, was elected president, and other officers were elected as follows: First vice-president, Dr. Joseph Smith, of Wausau; second vice-president, Dr. J. F. Pember, of Janesville; secretary, Dr. Rock Sylvester, of Waupun; treasurer, Dr. A. R. Hall, of Ripon. Next year's meeting will be held in Milwaukee.

Meetings of Medical Societies to Be Held in Philadelphia during the Coming Week.—Monday, October 23d, North Branch of the County Medical Society, Section in General Medicine, College of Physicians; Tuesday, October 24th, West Philadelphia Medical Association; Thursday, October 26th, Pathological Society, Northwest Branch, County Medical Society; Friday, October 27th, Neurological Society, County Medical Society, South Branch of the County Medical Society; Medical Club (directors).

Surgeons Wanted in the War Zone of Europe.—Major Louis Livingston Seaman, M. D., president of the British War Relief Association, Inc., calls attention to the scarcity of medical men in some of the armies of Europe, notably on the eastern frontier. He says that he is prepared to guarantee full officer's pay and traveling expenses to one hundred and fifty competent surgeons for six months' service in Europe, or until the close of the war. Major Seaman will be glad to furnish all details regarding the work; his address is 247 Fifth Avenue, New York.

Medical Society of the United States.—The first meeting of this newly organized society was held in St. Louis, Mo., on October 3d, 4th, and 5th. The first day's business consisted of committee reports on organization and arrangement, with the address of the president, Dr. A. H. Ohmann-Dumesnil, and a scientific program in the afternoon. The scientific program was continued through October 4th and 5th, with a reception for the president-elect, Dr. Emory Lanphear.

Ether Day at the Massachusetts General Hospital.—The seventieth anniversary of the use of ether as an anesthetic during a surgical operation was observed on Monday, October 16th, in the new Moseley Memorial Building of the Massachusetts General Hospital, Boston. Dr. Henry P. Walcott, president of the corporation and chairman of the board of trustees of the hospital, opened the meeting, and addresses were delivered by Dr. Herbert B. Howard, superintendent of the Peter Ben Brigham Hospital, Boston, and Dr. Haven Emerson, health commissioner of New York.

The Wesley M. Carpenter Lecture.—The late Dr. John B. Murphy, of Chicago, had been invited to give this lecture, and at the time of his lamented and untimely death the address was nearly completed. Dr. Philip H. Kreuscher, the collaborator of Doctor Murphy, presented the work as the joint effort of himself and Doctor Murphy, at the New York Academy of Medicine, Thursday evening, October 19th. The subject of the leeture was a Clinical and Experimental Study of the Metastatie Arthritides, based upon eight hundred elinical cases, and illustrated with lantern slides. Dr. George E. Brewer, of New York, gave a brief appreeiation of Doctor Murphy and his plaee in Ameriean surgery.

An Appeal for Help for Albania.—The Balkan Relief Fund, through its secretary, Mr. William Willard Howard, makes an urgent appeal for finaneial aid for Albania. Mr. Howard, who has just returned from his third trip to that country, says that already two hundred thousand women and children have died of starvation, and he believes that the entire population will die of famine and pestilence unless help is forthcoming. Mr. Howard is planning to return to Albania with a shipload of food. Arrangements have been made for the ship which is ready and waiting. Contributions in any amount, from the price of a loaf of bread upward, may be sent to the treasurer of the Balkan Relief Fund, the Reverend Frederiek Lynch, 70 Fifth Avenue, New York.

Personal.—Dr. A. H. Roler, of Evanston, Ill., has been appointed assistant to the American Embassy at Berlin. His duties will be to observe the conditions of British prisoners in Germany and of German soldiers imprisoned in Russia.

Dr. S. R. Klein has been notified by the Illinois State Civil Service Commission that at the civil service examination held in Springfield, June 10, 1916, he received ninety-two per cent. of the possible 100 marks, and is therefore first on the eligible list of eandidates for the position of State pathologist and biological chemist.

Dr. R. Tait MacKenzie, physical direetor of the University of Pennsylvania, who has been serving as a major in the Medieal Corps of the British Army for the past year, returned to Philadelphia a few days ago and will resume his duties at the university.

Dr. A. W. Downs, formerly professor of physiology at the Medico-Chirurgical College, of Philadelphia, has been appointed professor of physiology at McGill University, Montreal, and head of the department.

Dr. George Bain Jaekson has been appointed professor of anatomy at the State University of Iowa.

Dr. A. Gale Straw, of Manchester, N. H., returned home Oetober 2d, after serving for nearly a year with the Ameriean Ambulanee Corps in France.

Dr. Francis Leroy Satterlee, Jr., of New York, is suffering from the aftereffeets of x ray burns received in 1897. Since early summer skin grafting has been tried at various times without sueeess. Two weeks ago, the middle finger of the right hand was amputated, and on Monday, October 9th, another operation was performed. It is feared that it may be necessary to amputate the hand.

Health Insurance in Canada.—The National Liberal Party of Canada, led by Sir Wilfrid Laurier, has adopted a plank for compulsory health insurance of wage earners, maternity benefits to be included, as part of its program for the election following the conclusion of the war. Leading Canadian newspapers anticipate that in order to retain its popularity, the Conservative party will adopt a similar progressive program of social legislation. It is expected, therefore, that health insurance laws will be enacted in Canada in the early days of reconstruction. Compulsory health insurance of wage earners, based on joint contributions from the State, employers, and employees, has been established in Germany, Austria-Hungary, Russia, Great Britain, Holland, Norway, Rumania, and Serbia. In most of these countries both cash and medical benefits are provided for the insured workers, and effective campaigns for the prevention of sickness have become general.

Gifts and Bequests to Hospitals.—The Hospital for Deformities and Joint Diseases, New York, has received from Mr. Herbert Kauffman, of Pittsburgh, through Dr. H. C. Frauenthal, a gift of $1,000,000, to be used for the erection of a new building and for an endowment fund.

Among the gifts announced at the September meeting of the Yale Corporation is one of $10,000 for the Silliman Lectureship Fund, from the estate of the late Augustus E. Silliman.

The will of the late Eckley B. Coxe, Jr., of Philadelphia, contained public bequests amounting to $880,000, including one of $100,000 to the Children's Hospital, another of $10,000 to the same institution, one of $25,000 to the Pennsylvania Epileptic Hospital and Colony Farm, and one of $50,000 to the Orthopedic Hospital.

A contingent bequest of about $60,000 to endow the chair of bacteriology in Jefferson Medical College, Philadelphia, is contained in the will of the late Dr. James Y. Shearer, of Sinking Springs, Pa.

State Hospital Superintendents Hold Meeting.—The twenty-eighth semiannual meeting of the association of trustees and medical superintendents of the State and incorporated hospitals for the insane and feebleminded of Pennsylvania will be held on Monday and Tuesday, October 23d and 24th. Monday's session will be held in the Bulletin Building, Philadelphia, where the association will hold a conference with the Committee on Lunacy of the Board of Public Charities, and on Tuesday the association will meet at the State Hospital for the Insane in Norristown, Pa. Dr. Francis X. Dercum, professor of neurology at Jefferson Medical College, will read a paper entitled A Plea for the Intensive Treatment of Recent Cases, which will be discussed by Dr. John A. Lichty, of Pittsburgh, Dr. H. W. Mitchell, of Warren, and Dr. Frank Woodbury, of Philadelphia. Mr. William M. Donaldson, a trustee of the State Hospital at Harrisburg, is president of the association, Dr. H. W. Mitchell, superintendent of the State Hospital at Warren, is vice-president, and Dr. Henry J. Klopp, superintendent of the State Hospital at Allentown, is secretary.

Clinical Congress of Surgeons of North America.—The seventh annual session of this congress will be held in Philadelphia next week, with headquarters at the Bellevue-Stratford Hotel. The program of clinics and demonstrations for Monday will be posted on bulletin boards on Saturday afternoon, October 21st, and on each afternoon, beginning Monday, October 23d, the complete program of the next day's clinics will be announced in a similar manner, while a printed program will be issued each morning. While the chief attraction will be the clinics in the operating rooms of the thirty or more cooperating hospitals, a series of demonstrations, pathological, röntgenological, borderline subjects, etc., has been arranged, which it is believed will prove of great interest. On Monday evening, the presidential address will be delivered by Dr. Fred B. Lund, of Boston, and the new officers will be inaugurated, and on each of the three following evenings there will be general meetings. On Friday evening, there will be a public meeting under the combined auspices of the congress, the Philadelphia County Medical Society, and the Department of Public Health and Charities of Philadelphia.

Medical Society of the County of New York.—A stated meeting of the society will be held in Hosack Hall, New York Academy of Medicine, Monday evening, October 23d, at 8:15 o'clock. Dr. A. J. Rongy will read a paper on the Treatment of Contracted Pelves, with Special Reference to Pubiotomy, which will be discussed by Dr. George L. Brodhead, Dr. George W. Kosmak, Dr. Ralph Waldo, and Dr. J. Clifton Edgar. Dr. Louis Fischer will present notes on the Diagnosis of Abdominal Distention in Children and the subject will be discussed by Dr. Charles Gilmore Kerley, Dr. Henry Koplik, and Dr. Max Einhorn. Dr. Fred H. Albee will deliver an address on Experiences in Bone Surgery in France, which will be illustrated with motion pictures, and the subject will be discussed by Dr. H. H. M. Lyle, Dr. C. L. Gibson, and Dr. Samuel Lloyd. The 111th annual meeting of the society will be held on November 27th.

Army Medical Corps Examination.—The surgeon general of the United States Army announces that preliminary examination for the appointment of first lieutenants in the Army Medical Corps will be held early in January, 1917, at points to be hereafter designated. Full information concerning this examination can be procured upon application to the Surgeon General, United States Army, Washington, D. C. The essential requirements to secure an invitation are that the applicant shall be a citizen of the United States, between twenty-two and thirty-two years of age at the time of receiving a commission in the medical corps, a graduate of a medical school legally authorized to confer the degree of Doctor of Medicine, of good moral character and habits, and shall have had at least one year's hospital training as an intern after graduation. Applicants who are serving this postgraduate internship and can complete it before October 1, 1917, may take the January examination. In order to perfect all necessary arrangements for the examination, applications should be forwarded without delay to the surgeon general of the army. There are at present 228 vacancies in the Medical Corps of the Army.

Case Fatality and Crippling from Poliomyelitis.—A report issued by the Department of Health of the City of New York shows that the total number of cases of suspected poliomyelitis put under quarantine by the board up to October 11th, was 9,177; of these 250 were found, after careful clinical study at the hospital, not to be cases of poliomyelitis, and were deducted, leaving a total of 8,927 true cases. The total number of deaths recorded by the department was 2,343, a fatality of 26.24 per cent.

Cases may properly be divided into three classes, as follows: Those treated in the hospitals of the department of health, 4,474; total number of deaths, 653; case fatality, 14.59 per cent. Cases admitted to twenty-seven other hospitals in the city, 2,663; total number of deaths, 387; case fatality, 14.53 per cent. Cases in the home, 2,040, which may properly be subdivided into: Those left at home because home conditions were adequate for isolation, those which were too severe to be removed, and those not reported to the department until the death certificate was presented. Total number of deaths, 1,303; case fatality, 63.87 per cent. The high percentage of fatality in this group is mainly due to the fact that the major portion of the cases comprised in it were of the severest type.

From August 21st to October 13th there were discharged from the hospitals of the department 2,058 cases; of these 66 per cent. showed evidences of paralysis of some degree, 18 per cent. showed that paralysis had wholly disappeared, 15 per cent had not shown paralysis at any time in the course of the disease. Of 2,715 cases, followed up carefully in the homes, it has been found that 1,885 have a serious paralysis of one or both lower limbs and are unable to walk; 530 more were partially paralyzed in the lower limbs, although still able to walk: 273 had one or both arms totally paralyzed. Judging from the cases already visited by the agents of the relief societies operating under the Committee on Aftercare, between seventy-five and eighty per cent. of the cases with persistent paralysis will fall in the class of people who usually obtain medical services free.

Modern Treatment and Preventive Medicine

A Compendium of Therapeutics and Prophylaxis, Original and Adapted

THE THERAPEUTICS OF A PHARMACOLOGIST.

By A. D. Bush, M. D.,

Professor of Pharmacology and Therapeutics, University of Southern California.

Forty-first Communication.

VALVULAR DISEASE OF THE HEART.

In the consideration of heart affections space will not be taken for a discussion of prophylactic, dietetic, or hygienic measures, extremely important though all these are; attention will be paid, however, to the medicinal measures advocated, and to the pharmacological basis for such advocacy.

In aortic incompetency there is a relative innutrition of the tissues of the whole body, including, of course, the heart itself. In such a condition some measure is essential which will increase the volume of blood thrown into the arterial system per unit of ventricular contraction. Such a measure is the administration of digitalis. This drug adds such vigor to the contractions of the heart that an increased volume of blood is thrown into the aorta and its tributaries at each beat of the heart and is thrown forward with much greater vigor, so that there results a more nearly adequate distribution of the blood throughout the body.

Some objection has been raised to the use of digitalis in aortic valvular incompetency on the ground that the lengthened diastole permits increased regurgitation; but this objection involves a lack of recognition of two important points. The first is that the increased length of the diastole is possibly more apparent than real. The pause between two systoles is somewhat lengthened by digitalis, but a large part of this pause is occupied by delayed relaxation of the ventricles. Systole is more complete under the action of digitalis; and though diastole is also more complete, its relative time is actually briefer, owing to the less prompt relaxation from systole; in other words, diastole occupies a smaller percentage of the time involved in a cardiac cycle than before the administration of the drug. As a result, though there may be an actual slowing of the heart under digitalis (about 0.6 per cent., in my series of experiments with the normal human being), there is probably little additional opportunity for regurgitation from the aorta because of this factor.

A second point of advantage gained by the action of digitalis, which is of importance in regard to possible regurgitation, is the increased force given to ventricular contraction by this drug. If the elasticity of the arteries is not seriously impaired, the rebound from this ventricular thrust must inevitably tend to advance more fully the blood stream in the arterial tree, thereby limiting to a considerable degree the possibility of aortic reflux. These two factors warrant the use of digitalis in aortic incompetency. Then there is the additional consideration that the increased nutrition provided for the heart muscle itself renders available greater potential energy for the systolic effort.

In mitral incompetence there is increasing interference with the venous circulation, pulmonic when the initial lesion is sinistral, and systemic if the right side is primarily involved, although ultimately so in either lesion. Under treatment with digitalis there is usually a gratifying improvement which is explainable pharmacologically as follows: Digitalis acts on the whole musculature of the heart, as is shown by the beneficial action of the drug in auricular fibrillation; therefore we may expect an augmented auricular contraction in mitral incompetency after administration of digitalis, with a possible tendency toward delayed relaxation. Then, if we accept the tentative hypothesis that the wave of contraction affects the ventricle in the papillary muscles first, we should expect that a better approximation of the leaflets of the mitral valve would ensue from digitalis stimulation, provided there is no actual stenosis. The peculiar arrangement of the deeper sinospiral fibres indicates that in the more vigorous contractions of the digitalis heart, the major force of the blood stream tends to be diverted even more directly into the aortic antrum and thus somewhat more away from the region of the mitral orifice, thereby lessening the tendency to mitral reflux.

(*To be continued.*)

Complement Fixation in Acne vulgaris.—Albert Strickler, John A. Kolmer, and Jay F. Schamberg (*Journal of Cutaneous Diseases,* March, 1916) studied the question of etiology in acne vulgaris by means of the complement fixation test. A review of the literature of this disease shows that the causative factor in this affection is not as yet definitely determined. The various organisms employed as antigens in this study were Bacillus coli and the staphylococcus isolated respectively from the feces and the lesions of the patients with acne. Other antigens employed were the syphilitic antigens, staphylococci from abscesses, and colon bacilli isolated from the feces of children who were free from acne. Not only were acne cases tested, but also the blood in various nonacneiform skin diseases, and also patients without any skin affection. In this study the serums of 128 patients were used: of this number fifty-seven were patients with acne vulgaris, nine with acne rosacea, ten with seborrheic dermatitis, twenty-six with nonacneiform skin affections, and twenty-six from syphilis and other diseases, but free from cutaneous affections. In acne vulgaris, forty-eight, or 84.2 per cent., showed positive fixation with B. acne antigen; with the antigen of the staphylococcus derived from acne lesions the proportion of fixation was sixty-four per cent.; the same proportion occurred with the antigen of staphylococci from abscesses. With the antigen of the colon derived from the feces of patients suffering with acne, the proportion of positive fixation

was 63.1 per cent., while the control colon gave only thirty-two per cent. positive fixation. These results would seem to indicate an activity on the part of the colon bacilli in the pathogenesis of some cases of acne vulgaris. In acne rosacea, of which disease nine serums were tested, six, or 66.6 per cent., reacted positively with the Bacillus acne antigen, forty per cent. gave positive fixation with the staphylococcus, and fifty-two per cent. gave positive fixation with the colon antigen. In seborrheic dermatitis ten serums were studied; of this number three gave positive results with Bacillus acne, twenty-five per cent. gave positive results with staphylococcus. With the antigen of colon bacilli from acne patients, complement fixation occurred with forty per cent. of the serums, and in eleven per cent. with the antigen of colon bacilli of normal patients.

Nonacneiform Skin Diseases.—Twenty-six persons suffering from different forms of eczema, furunculosis, lupus, etc., were studied. In squamous eczema, the complement fixation tests were negative; in vesicular eczema, a number of positive results were obtained especially with the antigen of the cocci and Bacillus acne. These reactions, with those observed in acne rosacea and seborrheic dermatitis, may be interpreted as indicating that the staphylococcus and Bacillus acne of the skin exert a pathogenic influence in skin diseases other than acne vulgaris, although not intimately concerned in the latter. In syphilis and noneruptive diseases, the serums did not absorb complement with any of the bacterial antigens employed. This study (*Ibidem,* March, 1916) would seem to show that Bacillus acne is not specific for acne, but may be a normal inhabitant of the sebaceous follicles, capable of assuming pathogenic powers under favorable conditions in other skin diseases. The complement fixation reactions also tended to show the activity of the colon bacilli in certain skin diseases, particularly acne vulgaris, acne rosacea and seborrheic dermatitis. Just what role the colon bacillus plays in the pathogenesis of acne vulgaris no one can tell, but that it is a factor in a large group of cases seems to be borne out by serological findings.

A New Remedy for Syphilis, Luargol, or "102."—N. S. Bonard (*Lancet,* September 23, 1916) tells how, as the result of extensive investigations, Danysz of the Paris Pasteur Institute, produced a compound of dioxydiaminoarsenobenzol containing silver bromide and antimony. The silver increased the antiseptic properties of the original arsenical and the antimony was introduced for its spirochetocidal and trypanocidal properties. Animal experiments proved the new preparation to be ten times as active as arsenobenzol against trypanosomiasis and only slightly less than ten times as active against syphilis in rabbits. It was shown to have the further great advantage of having its therapeutic dose far below its toxic one. It was tried in man and was proved to be far superior to salvarsan or neosalvarsan in the treatment of syphilis. Bonard investigated the action of this new preparation in 100 cases of human syphilis in its different stages and obtained the best results in all cases. Thus, he found that it acted more rapidly than salvarsan or neosalvarsan, or any of the other organic arsenicals and failed to cause serious complications or reactions in any of the cases. It was given in solution in distilled water and sodium hydrate, either in concentrated solution or diluted with normal saline, and was injected intravenously in the same way as the other arsenicals. In syphilis without nervous complications the doses for men should be 0.15, 0.20, 0.25, 0.30, 0.30, 0.30 gram repeated at intervals of two to four days; for women the dose should be 0.10 gram increased as above to a maximum of 0.25 gram, and given at the same intervals. The injection should be made very slowly if the concentrated solution is used, and fairly so when using the diluted solution. The contraindications for its use are the same as for salvarsan or other arsenical, but it can be given in any case, whatever the conditions, if the initial dose is small enough and the increases are gradual. The best results were obtained from the administration of small repeated doses as outlined. Following the first dose slight fever without serious gastrointestinal symptoms or headache was often encountered. The patient should be prepared for treatment just the same as if salvarsan were to be given. Recently a sodium salt of the preparation, readily soluble in distilled water, has been prepared and is more convenient for clinical use. With this, as with all other organic arsenic preparations, we occasionally encounter a reaction with alarming symptoms of congestion of the face, dyspnea, urticaria, weakness of the extremities, convulsions, and headache. This reaction is never dangerous and is due to the formation of a fine precipitate in the vessels. It seems to be due to the condition of the patient's blood in respect to the several mineral salts present. It cannot yet be stated that luargol is the best remedy for syphilis, but it certainly is an advance over all other methods.

Syphilis of the Nervous System.—John A. Fordyce (*Medical Record,* September 30, 1916) considers that the best procedure is to give provocative injection of salvarsan to patients with a negative blood and a positive spinal fluid, and take the Wassermann at stated intervals. If the Wassermann remains negative, subarachnoid treatments may be begun at once. When both blood and fluid are positive, two or more injections of mercury should precede the intravenous administration of salvarsan, and after two or three doses of the latter the intraspinal injections are begun, supplemented by intravenous injections. In paresis, intraspinal injections are best begun after the first intravenous treatment, while the intervals between doses are regulated by the patient's reaction. Where subdural injections are well borne, they may be given in a series of four to six, one to two weeks apart, with a rest period of four to six weeks before giving another course. Ogilvie's modification of salvarsanized serum is now used by Fordyce, in which method salvarsan is added directly to the blood serum. Blood serum removed indifferently from patients acts as well as autogenous serum, and the most important step in the technic, next to absolute asepsis, is the use of a nearly neutral salvarsan solution. The blood is removed from an arm vein and centrifugated, the serum is pipetted off and again centrifugated to secure complete removal of red cells. To eight to ten c. c. of this serum 0.05 to 0.5 mgm. salvarsan is added, and the mix-

ture is incubated at 37° C. for thirty minutes. General paresis patients tolerate larger doses than those with tabes or other forms of cerebrospinal syphilis. The initial dose for tabetics should be 0.05 to 0.1 mgm., depending on the bladder involvement and the amount of pain present, and the quantity is gradually increased up to 0.2 to 0.3 mgm., if the patient will tolerate it. Activation of the lesions after the first injection is not a contraindication, but calls for care. There seems to be no limit to the number of injections that can be given. Success depends largely upon whether the morbid process is an active meningeal inflammation or a degeneration of essential nerve structures. Active inflammation with a strongly positive fluid gives a hopeful outlook, while degeneration with atrophy and sclerosis, with negative or weakly positive fluid, does not present so encouraging a prognosis. All patients at the end of the first year of infection should have a spinal puncture, whether or not they have any signs of the disease. If the fluid is negative to all tests, they may be assured that there is little danger of later development, whereas a positive colloidal gold test with persistent Wassermann in high dilutions, points to an impending paresis.

Sugar Content of the Blood in Diseases of the Skin.—Hans J. Schwartz, Walter James Heimann, and Harry C. Mahuken (*Journal of Cutaneous Diseases,* March, 1916) discuss the question of hyperglycemia in general, and show that in normal people sugar is present in the blood varying from 0.07 to 0.11 per cent. A definite increase appears soon after meals, and no blood test should be taken until three and one half hours after a meal. The method the authors employed was the micro method of Bang. A large number of different dermatoses were considered, and the diseases divide themselves broadly into two classes. First, those that show a marked increase, and second those that show no increase. In the first group are included acne, seborrhea and sycosis; and in the second group practically all the remaining dermatoses. Sixty cases of acne, seborrhea and sycosis were studied; of this number twenty-six showed excessive sugar and twenty-four did not. There were thirty cases of acne, twenty-three of the simpler type and seven of the indurated; of the former, seven showed marked increase, while of the latter, not one was normal. It has been shown that there is an increased sugar blood content, in association with or preceding the menstrual flow, which is transitory. This fact is of interest, as acne commonly becomes aggravated during the menstrual period. Twenty-four cases of seborrhea were studied, of which ten were normal, four on the border line, and ten showed a marked hyperglycemia. There were five patients suffering with sycosis vulgaris; of this number one was normal, and four showed a hyperglycemia. A summary shows that of patients with seborrhea and pilosebaceous disease forty-three per cent. had hyperglycemia. Of the other dermatoses, eighty-nine cases were examined, and but fifteen showed a high sugar content. There appears to be a force at work causing this association between diseases of the pilosebaceous follicles and an excess of blood sugar.

Treatment of Hemorrhage with Normal Blood Serum.—H. H. Forbes (*Annals of Otology, Rhinology, and Laryngology,* March 1916) states that an important point in operative work is that the prophylactic value of serotherapy is obtained twenty-four to forty-eight hours after the injection, and persists for at least three weeks, sometimes lasting two or three months, when the blood will have been found to have again the former anomalies of coagulation. In obtaining the serum, it has been observed that the specimen secured by centrifugating the blood is not as active as when allowed to clot in the test tube. Antitoxic serum has been used in cases with beneficial results. Human serum acts to advantage by protecting against anaphylaxis, no matter in what dose it is employed. However, direct transfusion from one person to another is fraught with certain dangers; especially is it desirable to ascertain that the serum of the giver does not agglutinate the red corpuscles of the recipient, or vice versa. Horse serum, which can be obtained in large amounts, seems to yield more uniformly satisfactory results than any other animal serum. Beef serum has a tendency to induce anaphylactic symptoms, i. e., chills and fever, cyanosis, vomiting, headache. To obtain full therapeutic action, serum older than two days should not be used. Precipitated blood serum in the form of powder has yielded good results in hemorrhages after tonsillectomies and turbinectomies.

Prophylaxis and Curative Treatment of Gastric Ulcer.—W. W. Hamburger and B. Halpern (*Archives of Internal Medicine,* August, 1916) find that a 2.5 per cent. solution of sodium chloride causes complete arrest of the action of pepsin; a 0.25 per cent. solution, little, if any, inhibition, and a 0.1 per cent. solution, actual acceleration of its action. Hydrochloric acid itself, while favoring peptic activity in 0.1 per cent. solution, almost completely inhibits it at 0.7 to 0.9 per cent. The chlorides of potassium, barium, ammonium, etc., act like sodium chloride. Certain other salts act in a much lower concentration than the chlorides. Thus, disodium hydrogen phosphate causes partial peptic inhibition in a one in 2,000 dilution, and complete inhibition in a one in 200 dilution. This is probably due to the fact that this salt is slightly alkaline, as pepsin is extremely sensitive to alkalies, and stronger alkalies such as sodium carbonate or hydrate, magnesium carbonate, and calcium hydrate act even more strongly on pepsin than sodium phosphate. It is suggested that sodium chloride or phosphate be used in the treatment of gastric diseases in which the control of peptic digestion may be desired, e. g., to promote healing in chronic ulcer. They may also be used in the prevention of gastric and duodenal ulcer. To control peptic digestion completely and permanently, however, the total acidity of the stomach must be completely neutralized, as hydrochloric acid protects pepsin from the inactivating effect of salts. For this purpose sodium carbonate, magnesium carbonate, and calcium hydroxide afford the maximum neutralizing value, and should be used in place of or in addition to the alkalies generally employed in gastrointestinal therapeutics.

Eusol in Septic Endocarditis.—J. Allman Powell (*Brit. Med. Jour.*, September 23, 1916) records the case of a young girl moribund from what was clinically a subacute, septic endocarditis secondary to erysipelas. Stock vaccine twice caused an abrupt fall in the fever but failed to affect the progress of the disease. One injection of forty mils of eusol was given intravenously, preceded by 300 mils of normal saline solution. The improvement was manifest in a few hours and went on to complete recovery without a repetition of the treatment. The patient has remained well for the five months since the treatment.

Gas Gangrene.—Cuthbert Wallace (*Brit. Med. Jour.*, Sept. 16, 1916) regards as the most important measures those directed toward the improvement of the circulation through the infected parts. These include the avoidance of tight bandages, the removal of hematomas and effusions, and the suture rather than ligature of the injured vessels. Amputation of an extremity should never be performed for crepitation in the subcutaneous tissues alone. When, however, the main blood supply to a portion of an extremity has been cut off the indication is for immediate amputation below the vascular lesion. In ordinary cases excellent results may be secured by free incisions combined with the complete ablation of all infected muscles.

Diarsenol in Tertian Malaria.—Frank C. Neff (*Jour. A. M. A.*, October 7, 1916) reports his experience of five cases of chronic, recurrent tertian malaria in children. All of the cases had proved wholly refractory to treatment with quinine. Diarsenol was given intravenously in doses of 0.1 to 0.4 gram. In all cases the initial dose of 0.1 to 0.2 gram controlled the symptoms and freed the blood from parasites. In two no further doses were given, as the patients were removed from hospital. In the others second or third doses were given as the parasites returned to the peripheral blood and paroxysms recurred after several weeks. All three, however, were permanently cured by the drug after two or three doses in all had been given. These results agree with those of some other recent writers in showing the effectiveness of arsenobenzol in malaria with quininefast parasites.

Perforated Celluloid as a Wound Dressing.—S. R. Douglas (*Lancet*, September 23, 1916) reports that in cases with large wounds and the loss of extensive areas of skin there is a great tendency for the ordinary dressings to adhere to the granulations and to cause great pain to the patient when they are changed, as well as to damage the healing tissues and delay recovery. This may be avoided by the use of a sheet of celluloid, perforated with holes one and a half mm. in diameter. Such sheets are readily obtainable in commerce. They are stiff, but may be softened and made perfectly pliable by soaking for a few hours in a five per cent. phenol solution. They are then applied to the surface of the wound, to which they will conform perfectly. When they harden they act as splints as well as preventing the adhesion of dressings; they reduce pain, provide for drainage, and when removed leave a healthy granulating surface which heals promptly.

Ventricular Premature Systole.—J. E. Greiwe (*Jour. A. M. A.*, October 7, 1916) points out that this form of cardiac irregularity is of exocardiac origin and, so far as the heart is concerned, is a functional disorder. Its commonest cause is some form of intoxication and it is frequently found associated with such conditions as constipation, intestinal stasis and toxemia, gallbladder disease, infections of the teeth, tonsils, nasal accessory sinuses and the genital tract, and with renal disease. Its treatment should, therefore, comprise the discovery and elimination of the cause in each case. Where such a plan does not give full relief and in cases in which no cause can be found, the condition can often be much improved by sufficient exercise out of doors. In still others resort may be had to digitalis in moderate doses to depress the activity of the vagus. It should be borne in mind, however, that digitalis should not be prescribed from the outset merely because a patient has extrasystoles.

Treatment of Toxemia of Dementia præcox.—Bayard Holmes (*Western Med. Review*, September, 1916) makes the suggestion based upon the study of this condition in a group of cases, that the putrefactive amines developed in the intestine by bacterial action play an important etiological role in dementia præcox. He therefore advocates the addition to the diet of foods and beverages which contain calcium and magnesium to combat the spasmophilic condition, and further, that the formation and absorption of the amines in the cecum be prevented by cecal lavage through an appendicostomy. This lavage should be given at bedtime and six hours after the last meal of the day. The lavage solution should consist of half a cake of dry yeast, emulsified in water and strained through gauze, fifteen grams of glucose, and water to make four litres. The fluid should be introduced at 104° F., and the patient should be encouraged to evacuate during the lavage each time the rectum fills. The yeast is used with the idea of deaminizing the toxic bodies and of preventing their formation.

Temporal and Subconjunctival Medication.—Robert B. Sellers (*Texas State Journal of Medicine*, September, 1916) advises the use of subconjunctival injections in certain ulcers with deep craterlike bases, or in serpigenous ulcers. In any acute infection following cataract operation this form of treatment is also indicated. Mercury cyanide, one in 5,000 to one in 4,000, has been used with success subconjunctivally in interstitial keratitis. In penetrating wounds of the cornea he recommends a solution of one in 1,500 mercury cyanide injected deeply beneath the conjunctiva at the outer canthus. The eye should first be cocainized and the needle inserted at an acute angle until it strikes the orbital plane, when the course is changed and the needle passed almost straight back into the deep tissues of the orbit. When giving injections of salt solution the strength should vary from two per cent. to five per cent. and the dose should be about fifteen minims. Two cases of toxic amblyopia due to alcohol and tobacco are reported, in which both optic nerves were white and the sight practically gone. One thirtieth of a grain of strychnine nitrate was injected once daily into the temporal muscles, restoring vision to normal in four weeks.

Complete Functional Restoration after Section of the External Popliteal Nerve.—Dujarier Bourguignon, and Perpère, at a meeting of the Société de chirurgie, Paris (*Presse médicale,* August 10, 1916), reported a case of complete section of this nerve due to a bullet wound, with additional incomplete paralysis of the internal popliteal, in which freshening of the neuromatous nerve ends seven months after the injury and suture with linen was followed in five months by reappearance of galvanic excitability, beginning return of voluntary movements ten months later, and later gradual complete restoration of function.

Treatment of Infantile Convulsions.—Clifford C. Grulee (*Texas State Journal of Medicine,* October, 1916) uses an anesthetic in extreme cases to control the convulsions. He prefers chloral hydrate given in an initial dose of from two to five grains, followed by one to two grains every four hours. It is given well diluted, and into the rectum, the buttocks being held together to prevent expulsion. Fifteen grains of calcium lactate given by mouth every four hours prove beneficial. The diet should consist of foods which are low in sodium and potassium salts. To promote the absorption and retention of calcium, it is well to give codliver oil and phosphorus, one half teaspoonful to one teaspoonful three times a day.

End Results in Cases Operated in for Salpingitis.—E. MacD. Stanton (*American Journal of Obstetrics,* June, 1916) discusses the results obtained in one hundred cases operated in by himself for pelvic peritonitis of tubal origin. From his experiences he deduces that the woman with a pelvic infection should be given a fair chance to recover without operation. Many cases clear up entirely if left alone. As a rule, therefore, the first attack should be treated conservatively until it is proved that convalescence is not going to be reasonably prompt. Recurrent cases, however, especially if there have been a number of attacks, should be subjected to operation at the first safe opportunity; likewise, patients who after one definite attack, have never had reasonably complete relief. On six of the author's patients, with the onset sudden and severe and the diagnosis uncertain, an operation was performed within thirty-six hours; acute purulent salpingitis and early peritonitis were found, and all recovered. Since, however, under rest in bed, with immobilization of the affected region, the temperature will usually reach normal about the eighth or ninth day, it is preferable in the average case to defer operation until a relative immunity against the infecting organism has been established. If, with a normal temperature, the general state continues to improve, the operation should, in fact, be deferred as long as absorption of the inflammatory exudates persists. In abscess cases, there usually develops after several days an afternoon fever of septic type. Here Stanton operates at once, and has had excellent results even when simple drainage of abscess cavities was alone justifiable. As for the method of operation, the author prefers the abdominal to the vaginal route. By the former route the offending tubes may in most cases be safely removed, if the indication exists. Yet the chances of an excellent result after simple but thorough drainage, as advised by Fenger, are so good that a patient's life should never be seriously endangered by attempts to do a complete operation. A point to be remembered, moreover, is that a unilateral salpingectomy done previous to infection of the other tube is usually followed by infection of this tube. Among forty-one drained cases, the results could in no way have been bettered by vaginal instead of abdominal drainage. Regarding preservation of the ovaries Stanton, viewing the general as well as the local results of their removal, is inclined toward conservatism and taking chances on the necessity of a second operation. He also argues against hysterectomy, which, beside the additional slight operative risk, may result in a vaginal atrophy or vaginitis far more troublesome than any uterine complications the patients are otherwise likely to have.

Treatment of Acute Anterior Poliomyelitis.—Louis Fischer (*American Medicine,* September, 1916) reports a series of twenty-five cases, only one of which was fatal. These cases were treated with intraspinal injections of convalescent human serum. The dose administered was from ten to fifteen c. c. Before injecting the serum about fifteen to thirty c. c. of spinal fluid was withdrawn. In cases where the fluid was under great pressure from forty-five to sixty c. c. were taken off. One injection of the serum usually proved sufficient, although the dose was at times repeated after twenty-four hours. The injections were followed by severe febrile reactions. Nausea and vomiting may develop. Excellent results were obtained with intraspinal salt irrigations at a temperature of 105° to 106° F. In order to induce sleep, three to five grains of chloral hydrate should be used.

Treatment of Genital Tuberculosis in the Male.—John H. Cunningham, Jr. (*Surgery, Gynecology, and Obstetrics,* October, 1916) concludes: 1. Post mortem and clinical findings show that in the majority of cases of genital tuberculosis, active tuberculosis exists elsewhere in the body, the genitourinary tuberculosis being a secondary infection. 2. In tuberculous epididymitis, tuberculosis of the vesicles and prostate usually exists on the corresponding side, whether or not the condition can be demonstrated by physical examination. 3. In cases of genital tuberculosis there is often tuberculosis of the bladder and kidney, and a cystoscopic examination with catheterization of the ureter should be made in each case, before the possibility of such associated infection can be eliminated. 4. The best treatment for the local condition, in most instances, is to remove the scrotal focus by epididymectomy or by castration; this should be followed by injecting the vas deferens with a dram of crude carbolic acid, in the hope of eradicating the disease from the genital tract. 5. The destruction of the local focus by this procedure is but the first step in the process of immunizing the patient against fresh outbreaks of the disease. Hygienic measures and the use of tuberculin should be used to aid further, in a rational way the immunizing power of the body against remaining lesions.

Miscellany from Home and Foreign Journals

Blood Cultures in Epilepsy.—William B. Wherry and Wade W. Oliver (*Jour. A. M. A.*, October 7, 1916) state that C. A. L. Reed described an organism obtained in cultures from the blood of epileptics and believed this organism to be the cause of the disease. He named it Bacillus epilepticus. Wherry and Oliver made repeated attempts to cultivate this, or other organisms from five of Reed's cases, but entirely without success. They also examined one of Reed's cultures and found it to belong, apparently, to the Bacillus subtilis group. H. Caro and D. A. Thom also report (same issue of the *Jour. A. M. A.*) on their inability to isolate any organism in 160 blood cultures from seventy epileptics representing all stages of the disease. They cite, further, a personal communication from M. M. Canavan, who also had uniformly negative results in an exhaustive bacteriological study of seventeen cases of epileptics in which there was post mortem examination.

Bronchiectasis of the Upper Lobes.—Thomas McCrae and Elmer H. Funk (*Jour. A. M. A.*, Oct. 7, 1916) state that, owing to inadequate differentiation between tuberculosis and bronchiectatic lesions, the opinion prevails that the apices and upper lobes are uncommon sites for bronchiectasis. This site for the disease is probably, however, more common than is usually believed, and the authors report five post mortem examinations in which it occurred. In four it was associated with tuberculosis and in all there was marked thickening and adhesion of the pleura, which is believed by the authors to be one of the important elements in the etiology of bronchiectasis. None of the patients showed evidence of syphilis. The clinical features of the disease should make its diagnosis possible even in apical cases. There is typically a long standing chronic cough, considerable expectoration which does not contain the tubercle bacilli, and constitutional disturbance is not marked. Röntgenographic study may aid in diagnosis and should always be undertaken.

Cardiac Disturbances in Left Sided Intercostal Neuralgia.—C. Lian, at a meeting of the surgeons of the Fourth French Army (*Presse médicale*, August 7, 1916), directed special attention to this condition, of which he has recently seen four cases. In the more severe forms, the cardiac disturbances are such as to constitute actual attacks of angina pectoris. In the less severe, there occur paroxysms of palpitation, or of dyspnea and palpitation, following physical exertions and at times accompanied by a dizzy malaise or syncopal tendencies. All these disturbances appear coincidently with a left sided intercostal neuralgia. Upon examination, the characteristic sensitive spots are noted, together with a permanent or orthostatic slight cardiac acceleration, or, at least, a very marked and persistent acceleration upon exertion. This symptom complex arises through the same pathogenic mechanism as peripheral pains in angina pectoris, but the reflex phenomena are inverted, a morbid state of the intercostal nerves or dorsal posterior nerve roots reacting through the rami communicantes, on the sympathetic fibres of the cardiac plexus. According to its situation, indeed, intercostal neuralgia may be complicated by other visceral disturbances—esophageal, gastric, or intestinal. Differentiation of these cases from instances of thoracic pain complicating certain cardiac diseases is based upon observation, in the former, of the characteristic points of tenderness in intercostal neuralgia, of involvement of one or more of the uppermost left intercostal nerves, of the sudden and simultaneous onset of the neuralgia and visceral disturbances and of a marked hyperesthesia to pin pricking in the zone of neuralgia. The area of hyperesthesia exceeds the precordia in vertical breadth anteriorly, but narrows down low in the axilla and posteriorly, finally passing into another broad area adjoining the spinal column and corresponding in situation and vertical breadth with the anterior area. The hyperesthesia extends beyond the midline for one or two cm. both anteriorly and posteriorly. The diagnosis is confirmed by treatment with analgesics and rest, the beneficial effects on the neuralgia and cardiac disturbances proving simultaneous. After three weeks to a month the patient may resume physical activity, though permanent disappearance of the symptoms may not occur for several months.

Etiology of Beriberi.—W. M. McDonald (*Journal of Tropical Medicine and Hygiene*, August 1, 1916) points out that the rice theory of beri beri is by no means applicable to all cases and outbreaks of the disease. In various outbreaks in the Malay Peninsula and Aden there was no change in the diet preceding the onset of the epidemics, and in a series of cases among prisoners at St. Helena the diet did not include rice. From a comprehensive study of the circumstances under which the disease occurs, the author has been led strongly to believe that beri beri is a specific infectious disease, transmission of which is dependent in some way on overcrowded sleeping accommodations. The disease experimentally produced in men and animals by subjection to a special diet is not true beri beri, but a multiple neuritis due to some deficiency in diet and simulating the true disease. Crowded sleeping accommodation is the only factor common to all recorded outbreaks of beri beri. In the Malay States all the tin mines have at some time been scourged with beri beri, the miners sleeping huddled together, whereas among the agricultural laborers there the disease is extremely rare. Beri beri is very common among sailors, who sleep in cramped quarters, and among coolies inhabiting common lodging houses. The decrease in beri beri in the Japanese army and navy, attributed to changed diet, coincides with hygienic improvements particularly in sleeping accommodation. The small incidence of the disease in women and in children and old people, which does not fit in with the rice theory, is explained by the fact that these do not work under crowded conditions. In an outbreak in a group of 580 men encamped near Aden an in-

crease in the number of cases at intervals of about two months pointed to an infectious disease with an incubation period of about that duration. The outbreak ceased after the institution of an isolation camp and the provision of larger tents on a larger area so as to prevent overcrowding. The evidence appears to point to a protozoal origin of beri beri, and to the bedbug or body louse as the agent of transmission. That attempts to transmit the disease by these insects have failed may be due to the necessity of the parasite undergoing a developmental phase in the insect host, as occurs in the mosquito in the case of malaria. As in yellow fever, the blood in beri beri may contain the infective organism only during a certain stage of the disease. At all events, improvement in housing and sleeping accommodations should be considered an especially important prophylactic measure where beri beri is endemic or epidemic.

Relation of Arteriosclerosis to Epithelial Malignancy.—Frank Warner (*Surgery, Gynecology, and Obstetrics,* October, 1916) concludes: 1. Of the 206 cases of carcinoma of all organs and regions examined, 105 showed arterial obstructive changes. This gives us substantially an equal division between endarteritis and normal vessels. 2. Fibrotic changes were present in 118 cases, or fifty-seven per cent. 3. Lymphocytic infiltration was present in eighty-five cases, or fifty-seven per cent. 4. Endarteritis and the anatomical changes of old age cannot be looked upon as a constant factor in the production of cancer as shown by the fact that normal vessels were present in almost half the cases. 5. The same holds true of fibrosis or even acellular connective tissue without fibrosis. 6. Lymphocytic infiltration, while present in less than one half of the cases, plays a role that is protective rather than etiological. 7. Certain biochemical factors of a local or internal or general type are probably causative of some cases of cancer.

Syphilis in the Southern Negro.—H. L. McNeil (*Jour. A. M. A.,* September 30, 1916) took routine Wassermann and luetin reactions in a large series of adult hospital cases without selection in order to determine the prevalence of syphilitic infection in the Southern negro. The results showed positive reactions to one or both of the tests in forty-two per cent. Since hospital cases are known to show a higher incidence of syphilis than is found in the healthy population as a whole, the tests were made also on 200 healthy negroes with the result that there were twenty-eight per cent. of positive reactions. The tests were also made on a group of healthy negro children and only ten per cent. of the cases reacted positively, showing that a large proportion of the adult syphilis was acquired. A similar study of white persons of a corresponding social scale showed about the same proportion of positive reactions as was found among the negroes. The cases studied in hospital were further analyzed, with the result that several diseases were found to be so commonly associated with syphilis, that the latter must be considered as playing a causal role. Such diseases included aortic aneurysm, aortic incompetency, a mild form of bone and joint pain, and fistula or stricture of the rectum.

Fractional Examination of the Stomach Contents.—Elbridge J. Best (*Jour. A. M. A.,* October 7, 1916) follows his critical review of the more acceptable methods of gastric analysis in the light of recent advances in our knowledge of the physiology of the gastric secretion, by pointing out the inadequacy of making a single extraction of a test meal at a given interval after it was taken. Such a plan fails to reveal the condition of gastric function. This, and other defects, can be overcome by the following technic. An Ewald meal of two slices of bread without crusts and two glasses of water containing twenty-five drops of a one per cent. solution of phenolphthalein is given on an empty stomach. Within half an hour a Rehfuss tube is passed and allowed to remain during the entire time of the examination. Samples of three to five mils of gastric contents are withdrawn at intervals of half, one, one and a half, two, and more hours after taking the meal. A syringe is used to remove the samples, and following their removal air is blown into the stomach to insure emptying of the tube. Each sample is titrated for free hydrochloric acid and total acid by the Töpfer method, and the last one is also alkalinized to test for the presence of phenolphthalein, which gives an index of the emptying capacity of the stomach. Such a plan is simple and gives a complete picture of the curve of gastric activity and the regurgitation from the duodenum. The ferments may also be determined if desired.

Notes on Radiography of the Gallbladder.—Nel MacLeod (*Archives of Radiology and Electrotherapy,* September, 1916) gives a review of twenty-nine cases in which the gallbladder when x rayed showed that seventeen presented abnormal shadows. Of these, nineteen were operated in and the interpretation was confirmed. Of the twelve cases with negative reports, one early case proved to have no calculus on post mortem examination, and a galibladder shadow was overlooked. In twelve of the cases, it was doubtful whether the symptoms were of gallbladder or of gastrointestinal origin. Nine of these twelve cases furnished no radiographic abnormality. Ten of the twenty-nine cases had typical biliary calculi and nine of these ten cases furnished positive radiographic results. The first ten were examined with ordinary tubes, the last eighteen with Coolidge tubes. The power was obtained from the public alternating current supply, a Siemens four k. w. transformer and a high tension rectifier being used. The spark gap was from four to four and a half inches, in one case being three and a half inches. With the ordinary tube, the milliamperage was two to three, with the Coolidge tube, eight to twenty-two. The length of exposure varied from ten seconds to two minutes. The a. c. distance from plate was twenty-three and a quarter to twenty-seven inches. The patients were all examined on their backs. The central ray was always directed perpendicularly to the plate, preferably through a marked point in the right epigastrium, one and a quarter to one and a half inch from the middle line. Compression was made in every case with a rubber cushion which, inflated fully, measured ten by seven and a half by seven inches; the cushion was contained in a double silk cover, thus always securing the same degree of inflation.

Relation of Migraine to the So Called Acidosis of Children.—J. A. Lichty (*Archives of Diagnosis*, July, 1916) points out that a mistake is commonly made in interpreting periodical vomiting in children and infants as being attacks of "acidosis" when in reality they are precursors of a permanent tendency to migraine. In children with cyclic vomiting Lichty has nearly always found a hereditary history of migraine in one or more forebears. In some, in fact, he has witnessed the transformation from cyclic vomiting to typical "sick headaches." The term acidosis is not comprehensive enough to cover cyclic vomiting. It is only a symptom, which may arise in any case in which a period of starvation has been gone through. Thus in cyclic vomiting of children with the usual acetonuria, the acetone, with the acidosis it betokens, is not the cause of the condition, but merely a result. In addition to seeing eight or nine cases of cyclic vomiting, later called acidosis, and finally passing into fully developed attacks of migraine, the author has obtained every now and then, among seven hundred cases of migraine, a history of bilious attacks with obstinate vomiting in childhood and migraine coming on at puberty.

Significance of Apical Pleuritis in the Diagnosis of Pulmonary Tuberculosis.—E. Sergent (*Presse médicale*, August 24, 1916) accords much significance to pleuritis over the lung apex, not only in the diagnosis of tuberculosis, but in the differentiation of its various stages and forms. It accounts, moreover, for certain wrong and conflicting conclusions commonly reached in interpreting physical signs at the pulmonary apex. At autopsy the apex is often found more or less adherent to the parietal pleura and chest wall. Pain in the inner part of the supraspinous fossa and above and below the clavicle, persistent and unaccompanied by indications of neuralgia or neuritis, is a pleurodynia and signifies apical pleuritis. According to the extent and thickness of the latter, percussion is negative or reveals a more or less complete dullness; palpation yields corresponding results, and inspection may show a sinking in of the infraclavicular and supraspinous soft parts. Auscultation, where the pleural thickening is marked, may show reduction or abolition of the vesicular murmur, and in acute or subacute pleuritis, reveals slight, circumscribed, friction sounds, which the inexperienced or careless may mistake for rales and dry crackling sounds. X ray examination shows a veiled or opaque condition at one or both apices; if coughing fails to remove this, either a marked pleural thickening or an apical consolidation exists, whereas if it causes the shadow largely to disappear, there is slight pleural thickening with the parenchyma remaining free. Pupillary inequality, the pupil on the affected side being dilated or contracted according to whether sympathetic irritation or paralysis exists on that side, and also a supraclavicular adenitis, just behind the clavicle and against the outer margin of the sternomastoid muscle, are frequent accompaniments of apical pleuritis. The adenitis is noted in the form of an elongated node, practically parallel with the clavicle, varying in size from a small bean to a Lima bean or even larger, usually hard when small and soft when large, the latter condition indicating as a rule an active pleural lesion, while the small, hard node signifies an old, healed one. Anatomical and post mortem studies showed that this type of glandular enlargement is far more closely related to pleural than to pulmonary disease, and when present is consequently a sign of apical pleuritis. The latter, revealed by coincidence of a number of the signs already mentioned, is to be taken as an important indication of tuberculous disease and is one of the chief stigmata of an old, cicatrized lesion. Whether tuberculosis is active at the time is recognized through the general signs as a whole, the fever, loss of weight, anemia, dyspeptic disturbances, low blood pressure, and endodermal tuberculin test.

Heart Affections in Soldiers.—J. C. Meakins, Thomas Lewis and others (*Brit. Med. Jour.*, Sept. 23, 1916) found that by physical signs alone it was possible to eliminate about forty per cent. of the men admitted with cardiac symptoms as unfit owing to definite crippling organic disease of the heart. Of the remainder, the majority had indefinite physical signs and symptoms, such as dyspnea, palpitation, vertigo, or fainting. The determination of the fitness or unfitness of such men for service, and of their limitations when fit, was possible only by careful determination of their capacity for enduring mild, graded exercise. The several exercise tables used are given, as they were found to be easy to execute and gave very satisfactory results, both in grading the heart's capacity and in developing that capacity to its maximum. By these exercises an additional five per cent. of the original group were found unfit for service. In all about fifty to fifty-five per cent. of soldiers suffering from cardiac symptoms were found fit for some form of military duty by the tests. All of the men in this group were suffering from what has recently been called "irritable heart."

Distribution of Typhoid and Paratyphoid Infections.—C. J. Martin and W. G. D. Upjohn (*Brit. Med. Jour.*, September 2, 1916) have made observations upon 627 patients and 151 normal persons, carefully controlled quantitative agglutination tests being used for diagnosis. In many cases these were also controlled by the isolation and identification of the organisms. Agglutination was found for one or more of the enteric group of bacilli in 464 cases, of which 213 were against paratyphoid A and 113 against paratyphoid B. Of 138 cases agglutinating only Bacillus typhosus, twenty-five were cases of typhoid fever, the remainder being accounted for by previous inoculation. On the basis of these observations and the returns for almost 100,000 men, the incidence of typhoid fever amounted to less than one half of one per cent. of all forms of sickness. This low figure was evidently due to prophylactic inoculation. An interesting observation was made in the course of these studies which showed that infection by one of the paratyphoid organisms often produced a rising typhoid agglutination titre in inoculated subjects which preceded the development of paratyphoid agglutinins by a week or two. This proved a confusing element in the use of the agglutination test for diagnosis.

Proceedings of National and Local Societies

NEW YORK ACADEMY OF MEDICINE.

SECTION IN GENITOURINARY SURGERY.

Stated Meeting, Held January 19, 1916.

Dr. A. R. Stevens in the Chair.

Narrowing of the Lower End of the Ureter Due to Gonococcus Infection.—Dr. Leo Buerger presented a case which he regarded as unusual, since he was able to demonstrate a narrowing of the lower end of the ureter, caused by infection with gonococci. Cases of this sort were rare, and the presence of gonococci as the causative agent had been seldom demonstrated. The patient, L. B., single, male, was referred to Doctor Buerger, the complaint being that for more than one year the urine had been cloudy, in all probability the result of a gonorrheal infection, because there was a history of infection of the eyes at the onset of the disease. Gonococci had, however, not been demonstrated and the patient had been treated as having a case of cystitis, possibly tuberculosis, during the whole time.

Cystoscopic examination revealed a remarkable bladder picture, the left half of the trigone, the paratrigonal region, and the sphincteric region being occupied by numerous red follicles, some of which had undergone cystic degeneration. Urine obtained from the right kidney showed a normally functioning organ, the urine being negative, except for a trace of albumin. Ureteral catheterization of the left side was somewhat difficult, owing to a distinct narrowing of the lower end of the ureter, no flow of urine being obtained until the catheter was pushed up to a point twenty cm. above the meatus. When this point had been passed by the ureteral catheter, a copious flow of turbid and slightly bloody urine was obtained. The first specimens collected during a period of ten minutes were discarded and the last specimens were submitted to the bacteriologist, who reported pus and a pure culture of gonococcus. Gonococci were also demonstrable in the bladder urine. The diagnosis of gonorrheal cystitis, gonorrheal ureteritis, possibly pyelitis of the left kidney with distinct inflammatory stenosis of the lower end of the left ureter, was made. Subsequently the patient received autogenous gonococcus vaccines, and at a second cystoscopy, the left ureter and pelvis were thoroughly washed with ten per cent. argyrol, the same stenosed condition of the lower end of the ureter having been encountered. The improvement was almost immediate, and within three weeks the urine was clear, and gonococci were absent.

Doctor Ware asked whether Doctor Buerger thought it was an ascending infection, or whether it was in some way metastatic. It was difficult to explain how the condition could be unilateral if it resulted from an ascending infection. Furthermore, the stenosis being rather far distant from the ureteral orifice, pointed rather to its being a descending infection.

Stricture of the Ureter.—This paper, by Dr. Guy L. Hunner, of Baltimore, appeared in our issue for July 1, 1916, page 5.

Dr. Henry Dawson Furniss was much pleased to hear what Doctor Hunner had said, for his large experience with this condition in women had given him better facilities for appreciating strictures than in the male, for in women he was able to use much larger instruments. Many of the strictures that they encountered were of large calibre and offered no obstruction to a No. 6 or 7 catheter. His first case had been operated in by a good man in New York city for gallbladder disease. The patient had had an ureteral stricture, at the vesical end, with dilatation of the ureter and renal pelvis. He dilated the stricture, but it could not be kept open. Subsequently he removed the kidney, and four months later she had an attack on the other side. When she had the attack in the one kidney she went through a cycle lasting ten days. She would come in almost blinded, with intense headache, and urinating only nine or ten ounces daily. She would be dilated with a No. 26 French bougie through a Kelly cystoscope, and then she would have a bad time for twenty hours. The next day the urine output would be twenty-five ounces, and she would feel better. At the end of ten days she was back at the beginning of the cycle, showing ureteral obstruction.

Another case showed the same kind of stricture. One of these was from a girl who at first had attacks every four to six months, and finally had them every Wednesday. The specimen showed very little cortex. It was doubtful whether the kidney held over 100 c. c. There was obstruction in the ureter, just at the pelvic junction. In the other one, the cortex was a little thicker, but there was a definite stricture below the pelvis of the kidney.

Doctor Furniss said that Doctor Hunner had done good work in showing that many of these kidneys could be saved, and his results were better than most of the New York men had had. He had also brought out the fact that most of these strictures were apt to occur in the so called rheumatic conditions. Doctor Furniss said he himself believed that the arthritic conditions were dependent upon an infected kidney. He had had a number of cases of arthritis which had cleared up after the pyelitis was cured. One of these patients came in complaining of pyelitis; she had a temperature of 104° F. and complained of pain in her knees, and she also had endocarditis, etc.

If a stone had come down the ureter and had become impacted, it would usually cause a stricture; if the stone was not imbedded in the tissues, it would move up and down, and as soon as it was displaced the stone might get into the kidney. That idea might seem rather far fetched, but in the Post-Graduate Hospital this year he had demonstrated a stone in the ureter, with none anywhere else. The patient was operated upon and the ureter was found to be dilated. This was explored, but no stone was found, and he thought that possibly the house surgeon through some manipulation had loosened the stone and that the patient had passed it. Before she left the hospital, she was radiographed and a stone was revealed in one of the calices of the kidney. She refused further operation and left the hospital with the stone in the kidney.

Doctor Lowsley said that apropos of Doctor Buerger's inquiry regarding specimens, it might be interesting to know that he himself had examined some 350 specimens rather minutely, measuring that portion of the ureter which passed through the vesical wall, and had found the average of all these cases to be 1.7 cm. There was a considerable variation, ranging from 0.75 to three cm. Out of these cases he had found eight, where there had been a very definite and decided stricture of the ureteral orifices, and all the strictures which had been acquired had been bilateral. In all of the cases there was decided induration of the ureter and narrowing of the ureteral lumen. He had no specimens where there was a normal ureteral orifice with stricture above.

Dr. Paul Pilcher felt very much confused on this subject and was inclined to agree with Doctor Buerger. He had examined many cases in both males and females, and frequently found these cases of stenosis in some portion of the ureter. Aside from an occasional case, he had not met with constriction or stenosis in the lower portion of the ureter. The cases of hydronephrosis, aside from those due to stone or tuberculosis, or actual secondary inflammatory periureteritis, had been due mostly to anomalies, or twists or bends of the ureter—actual anatomical deviations of the ureter. He had followed Doctor Hunner's work for years and had been much impressed with it. He did not think that they could judge their cases intelligently without going to Baltimore and seeing them handled by Doctor Hunner.

Doctor Pilcher could not understand the pathology of the condition. It did not seem logical that a stricture of the lower ureter should occur after an attack of tonsillitis. He himself was more impressed with the possibility of some connection with the intestine or to a condition in the pelvis or bladder wall as being the origin of some of these infections. He had never seen a real stricture with round cell infiltration which could be permanently dilated with a soft bougie. If there was an actual stricture with round cell infiltration, with a cicatricial formation, they must use a solid instrument, such as the olive bougie, to dilate it permanently. His own experience with stricture had been mostly with anatomical deviations. He wanted to go to Baltimore and see these cases in order to be more thoroughly convinced.

Doctor Bugbee had been much interested in Doctor Hunner's work and was desirous of knowing more of the etiology and pathology of these conditions, but he could only repeat what had been said, that it was a question of what was called a stricture. They often met with narrowings in the ureter. They were common; and he had found that if a No. 7 F. catheter could be passed, it could not properly be called a stricture. The question of diagnosis was an important one. He had tried the direct method in some cases, and believed that very often with the indirect cystoscope they could pass obstructions that could not be passed with the direct instrument. He would not feel like making a diagnosis with a stiff instrument such as Doctor Hunner had shown. Prolapse of the ureter and distortion were so common that it was important to use a soft catheter which would go through a very narrow kink.

An x ray picture should be taken with such a soft catheter in position, with patient first lying down and then standing up. He had often found in the female with an infected kidney that pus and débris would collect in the lower part of the ureter and cause a temporary obstruction, and that in a few days after passing a catheter the symptoms would disappear. Such a case might well be mistaken for a stricture. The metal bulbs devised by Doctor Buerger were valuable aids in making a diagnosis of stricture of the ureter. They ought to have a standard of some kind to go by to determine what form of obstruction should be considered a stricture. If they considered No. 7F as a stricture, they would probably see a great many of them It was a most interesting subject, and he had greatly enjoyed Doctor Hunner's address.

Doctor LeWald said that the lack of definite cicatricial tissue led him to believe that there might be an analogy between cardiospasm of the esophagus and spasm of the lower end of the ureter.

Doctor LeWald was very much interested in the presentation by Doctor Hunner of a concretion in the vermiform appendix. He had seen two similar cases recently. In one case by means of the Röntgen examination Doctor LeWald had suggested the possibility, and Doctor Douglas had found the concretion just outside a ruptured appendix. In the other case Doctor Douglas had operated upon a ruptured appendix and found a concretion which on x ray examination proved to be of sufficient density to have made discovery possible prior to operation, had there been an x ray examination. They ought to keep this possibility in mind and always have the patient examined with the rays where time permitted.

Dr. Victor Pedersen said that it was impossible to add anything to what had been said. He agreed with Doctor McCarthy that in some of Doctor Hunner's cases there might be an undoubted stricture, by which he meant a definite fibrous change in the mucous membrane itself exactly as a stricture in the urethra was constituted. Doctor Buerger's suggestion, that these cases be cystoscoped in the indirect method aso, before making a definite diagnosis, was important and practical.

For many years there had been a recognized standard of calibre for the urethra and there should be one for the ureter. They knew that the ureter was narow at the pelvis, where it originated from the kidney, where it entered the bony pelvis at the pelvic brim, then where it passed forward to reach the bladder and again at its outlet. In that connection, what Doctor Bugbee had said was valuable; they should agree upon some size which was considered normal.

His own work was about equally divided between the two sexes, and he had two women now under his care with stones in the ureter exactly where it turned forward along the pelvic floor to enter the bladder, and he had been wondering whether they might have been held by some change in the uterine appendages or by the uterine artery where it crossed the ureter, making compression, and stimulating stricture formation.

Doctor Hunner expressed his appreciation of the discussion and of the criticisms which had been offered. It would be a sad state of affairs for a man

to go away from home and read papers before other societies and expect to get off without criticism. Criticism did great good and made them think more acutely and observe more closely.

Regarding Doctor Buerger's comparison of positions and methods in cystoscopy, he had always thought the knee chest position, which carried the kidneys down toward the diaphragm and tended to straighten out any ureter kinks, was a better position than that with the patient on the back, which conduced to laxity of the ureter with chances for the renal catheter to catch in the pockets or kinks. It would seem that they would be more liable to get such temporary obstructions by the male than by the female method.

As to what sort of an obstruction should be called a stricture, he did not know what was the standard in New York. He himself found obstruction to a catheter almost every day, but when they found an obstruction at a certain level every time they tried to catheterize a given patient and felt a grating in going through the scar tissue as if going past a stone, it was difficult to see how the condition could be called anything but a stricture. Doctor Buerger had asked about the pathological material. The speaker was glad his patients had not furnished pathological material, but he had studied ureter strictures from the pathological laboratory. He did not know what better evidence could be required than that found in these retrograde operation cases and in anastomoses of the ureter to the bladder. The operator had difficulty in getting away the infiltrated tissue and often had difficulty in determining which was stone and which was stricture, because of the dense area of chronic infiltration.

He did not see what better evidence could be desired; given a definite point of obstruction to the catheter tip, where they could actually feel the "hang" when the wax bulb was going and coming, and then hydronephrosis, and the relief to the patient and shrinking of the dilated pelvis after dilatation. They could hardly ask for better evidence. In the young woman of whom he had spoken as having but one kidney, no stricture could be recognized for over a year, but one was finally found. When she first came, the pelvic contents were only eight c. c., but finally they came up to twenty-two c. c. Such evidence seemed sufficient.

As to the gynecological conditions, they would naturally think that with all the operations in the pelvis pathological conditions were created in the ureters, but he had not included any such cases in the list reported. There was no such evidence in any case, excepting one which had been operated in for some pelvic condition, and a nurse had put in a strong carbolic solution as a bladder instillation. That was a case of postoperative stricture in the bladder wall, probably due to the carbolic burn.

As to the size of the pelvis: Of the sixteen noninfected cases, the pelvis was measured in ten instances, and averaged nineteen c. c. He had mentioned in his paper that there were three only of about normal size, or respectively of eight, eleven, and twelve c. c., but the others held fifteen to thirty c. c. One, which he had mentioned especially, measured 385 c. c., and was free from infection, but that was in a class by itself. Of the eighteen infected cases, the pelvis was measured in fifteen instances. Four were approximately normal, and averaged 130 c. c.

Stated Meeting Held February 16, 1916.

Dr. A. R. Stevens in the Chair.

Colon Bacillus Infection of the Bladder.—This paper by Dr. R. T. Morris was published in the Journal for April 1, 1916.

Doctor LeWald said that Doctor Morris had spoken of the association of Bacillus aerogenes capsulatus. It seemed possible that the aeroform bacillus would produce gas in the urinary tract, and that might be elicited by the x ray. That was now being done abroad in wounds infected by gas bacilli. Gas cast a very definite shadow in the radiograph, either by pushing aside the tissue or, as Doctor LeWald thought, the rays might become intensified in passing through the gaseous substances. This had made it possible in gas infections of the extremities to recognize the gas even before a culture was obtained. It was possible that Bacillus capsulatus aerogenes infection in the urinary tract might make itself recognized in that way.

Doctor Heyd, referring to Doctor Morris's idea about intestinal toxemia being a factor in the production of infection of the bladder, said that they had observed a number of cases of bacilluria in conditions of chronic constipation. Bishop had found that right sided bacilluria was twelve times more common than left sided, and the anatomical demonstration by Franke of connecting lymphatics between the cecum and right kidney lent additional significance to the probability of bladder infection from conditions of chronic intestinal stasis. In the cases that had been studied there were intermittent attacks of fever and prostration that might be interpreted as attacks of pyelitis.

Doctor Barringer asked if he had understood Doctor Morris to say that children treated one way or another would readily clear up. This was at variance with the experience of Cabot. He found that they readily cleared up so far as symptoms and pus in the urine were concerned; but a large number of these cases, examined years afterward, showed cultures of colon bacillus in the urinary tract, though free of symptoms.

Dr. Victor Pedersen said that the duration of the lesion was of some importance. He had had two such patients pass through his hands, one a child of twelve years, who had had a lesion for a year and a half, and a large number of wild diagnoses had been made, including malaria, etc. She had undoubtedly very badly damaged kidneys, worse on one side. In that case, dietetic and other efforts, including a liberal administration of bacterins, had had no effect. She died of systemic absorption. Operation was refused. She tolerated the vaccines well, but they did not reach the lesion. She ought to have had surgical intervention, but it was declined.

The other patient was a woman who had had the disease for a shorter period and was cured in a short time by the use of bacterin. It was probably a question of how badly the kidneys were damaged which decided how good was the response to the bacterin.

Referring to the case mentioned by Doctor Morris as having bacilluria without symptoms, Doctor Pedersen had seen an adult who showed bacilluria most of the time, but without symptoms of absorption, except a general out of sorts condition, and who had been cleared up by Bacillus bulgaricus given by mouth. Undoubtedly, she had intestinal stasis, and absorption was going on. The subject of the paper was interesting, and Doctor Morris was to be congratulated.

Doctor MORRIS, referring to the point brought up by several of the speakers, said that the colon bacillus might be present in the urine for months or years without showing symptoms. If one happened to find it, it might explain many obscure symptoms dependent upon some focal infection which needed attention for its own sake.

Rhabdomyosarcoma of the Prostate Gland.—Doctor J. BENTLEY SQUIER read this communication.

Doctor MACKENZIE said that just three years ago he had seen a patient with a history somewhat like that of Doctor Squier's patient, who gave a history of terminal hematuria coming on three months earlier. There was some enlargement of the prostate, per rectum, with absolutely no nodules, so far as could be determined. The prostatic tumor was removed suprapubically. It was distinctly encapsulated. The first microscopical diagnosis was lymphosarcoma, with some muscle fibres. He did not feel satisfied to report this as lymphosarcoma, and would like to have Doctor Squier see the specimen. The end of the patient was very much like that of Doctor Squier's patient. He made a good recovery and was lost sight of for a while. Four months later, Doctor Mackenzie wrote and received in reply a very incoherent letter, of which he could make nothing. Later, he wrote to the physician who had referred the patient, and found that the man was in a sanatorium. That was about six months after the operation. Doctor Mackenzie then wrote to the sanatorium and learned that the man had died on the day the letter was written. So far as he could learn, the man died of metastases in the brain or in the meninges. Death occurred about six months after operation.

As to the radical removal of the prostate through the perineum for malignant growths, and the subsequent incontinence, Doctor Mackenzie had had two patients in the service at Bellevue who became perfectly continent after such an operation.

Dr. VICTOR PEDERSEN asked if there was any relation between this and embryonal tumor of the kidneys. It would be interesting to know Doctor Wood's views, because all tumors known to contain embryonal tissue were extremely malignant, exactly as this tumor removed by Doctor Squier was vicious.

Doctor BEER had seen one sarcoma, and the report received was "spindle celled sarcoma"; he had also seen one case in a child which he took to be sarcoma. During the past week he had had a patient who seemed to have a large tumor starting in the prostate, possibly sarcoma. No operation was possible. Doctor Squier might like to see him.

It was gratifying to hear that Doctor Squier had obtained such excellent results, so far as control was concerned with Young's total prostatectomy. Some time ago Doctor Beer wanted to send a patient to Doctor Young to perform this operation, provided that he could assure the patient he would be continent, and Doctor Young wrote that he could not operate with any confidence. He stated recently that he had had one case in which he operated, and the patient was continent. Doctor Beer understood Doctor Squier to report nineteen cases which were satisfactory from this standpoint. If so he was to be congratulated. Was it a proper procedure? He preferred to operate in carcinoma of the prostate and neck of bladder from above downward. He did a wide Wertheim procedure through the pelvis, getting out the glands first, and taking out the bladder, seminal vesicles, and prostate in one mass by the combined abdominoperineal route. The patient was incontinent, but wore a tube in each ureter and kept dry. He had shown one such case recently a year after operation. The man was comfortable and had had no recurrence.

Doctor BARRINGER wished to substantiate Doctor Squier's end results. He had seen the patient a short time ago, when he had had enormous metastases in the perineum.

Doctor HEYD said that in the discussion at the time of operation various arguments for radical operation had been discussed. At the conclusion of the operation, it was considered that a most complete and radical operation had been done. The very rapid recovery without incontinence was a matter of gratification and the prognosis seemed hopeful. The fulminating character of the metastasis and the rapid recurrence pointed to an unusual degree of malignancy.

THE AMERICAN ASSOCIATION OF IMMUNOLOGISTS.

Third Annual Meeting, Held at Washington, D. C., May 11 and 12, 1916.

The President, Dr. J. W. JOBLING, of Nashville, Tenn., in the Chair.

(*Concluded from page 770.*)

Diagnosis and Treatment of Septicemia.—Dr. OSCAR BERGHAUSEN, of Cincinnati, averred that the term, septicemia, was preferable to bacteriemia. Pyemia was simply a complication of septicemia. They had made blood cultures in fifty cases having symptoms clinically resembling septicemia. Of these, fifty-seven per cent. were positive, the streptococcus being the prevailing organism, although the staphylococcus was occasionally found, or a bacillus of the colon type in terminal infections. Of twenty-three patients with a positive blood culture, seventy-four per cent. died and twenty-six per cent. recovered. Of seventeen patients with a negative blood culture, thirty-five per cent. died and sixty-five per cent. recovered. This showed the value of the blood culture in suspected cases of septicemia, not only in the diagnosis, but also in a prognostic sense. The total white count varied from 7,100 to 25,000 in the patients who recovered; from 7,000 to 30,000 in those who died. Ordinarily in this series a low white count indicated a bad prognosis. However, this was not invariably the rule. The differential

white count was of the greatest importance. When the polymorphonuclear count approached ninety per cent., particularly when the white count was low, the prognosis became grave. In most of these cases the antistreptococcic serums obtainable on the market were employed, before the writer saw the patients; in none was a cure reported. In thirteen patients autogenous vaccines were employed in addition to the regular symptomatic treatment, and of this number, seven recovered. In true septicemia, the prognosis depended upon the state of health of the patient, the type of organism causing the infection, and the complications which might develop. The longer the course of the disease, the more favorable the prognosis. These patients should be treated as consumptives, at least they should have plenty of fresh air and should be fed as liberally as possible without deranging the digestion. The hot pack was indicated in septicemia marked by high temperature and erythema, and in the absence of more serious complications, with stimulation before and after the pack. Digitalis might be employed to enforce the heart's action in the beginning, though they could not thereby prevent the onset of the endocarditis. Of the antipyretics, quinine was the most important and should be used in small doses and often. Apparently good results had been obtained by hypodermoclysis. They believed the continued use of autogenous vaccines was justified. Spinal puncture was indicated when symptoms of meningismus developed.

Intravenous Therapy: The Use of Sensitized Bacterins Intravenously, Especially in Pneumonia.—Dr. William Egbert Robertson, of Philadelphia, Pa.; Dr. Claude P. Brown, and Dr. Allen G. Beckley, of Glenolden, Pa., recalled that up to the present time bacterins had been given therapeutically most frequently in chronic, localized infections, less often in general infections. Treatment had usually been with the nonsensitized type and the mode of administration had been subcutaneous. Very little clinical use had been made of the intravenous administration of sensitized bacterins. Because sensitized bacterins, from a theoretical standpoint, seemed to give a quicker response in the production of immune bodies, and because with the intravenous mode of administration an immediate action of the bacterin might be secured with no attendant local reaction, the authors had employed serobacterins intravenously in a series of cases.

One case of typhoid, treated in this way, gave severe reactions after injections of the bacterins. Satisfactory recovery occurred. Severity of reaction after the intravenous use of sensitized bacterins was typical in typhoid cases in general and was much more pronounced than in pneumonia treated in the same manner. In eleven cases of pneumonia two procedures were followed, some patients receiving a polyvalent bacterin composed of sensitized pneumococci alone, others a mixture of sensitized pneumococci, streptococci, and staphylococci. Those receiving the pneumococci alone experienced no sharp reaction, while those receiving the mixed bacterin reacted with chill and subsequent rise in temperature, accompanied by a marked change in the total white count and polynuclear increase. Of the eleven cases treated, ten ended in prompt recovery. The eleventh case, which terminated fatally, was complicated with nephritis. In the cases treated no detailed attempt was made to study the type of the infecting organism, but of seven cases in which this was done three were of type I, three of type II, and one of type III.

Treatment of Tuberculosis pulmonalis by Tuberculin.—Dr. A. N. Sinclair, of Honolulu, Hawaii, considered that the most notable proof of the value of tuberculin was seen in the difference in the results obtained at Leahi Home before and since the adoption of tuberculin treatment. No attempt had been made to classify the cases, because as soon as classification was attempted, considerable opportunity for error was offered. Out of 309 cases before the period tuberculin was used, 27.2 per cent. of patients either improved or were able to return to their former occupations, while out of 506 patients treated after tuberculin was adopted, 50.1 per cent. were enabled to resume their former occupations. Another proof of the value of tuberculin was the almost immediate and continuous improvement that had occurred in many cases that did not receive treatment at Leahi Home, but who had tuberculin treatment. Patients having suspicious signs of tuberculosis, but in whom the diagnosis lacked confirmation, offered golden opportunities for the administration of tuberculin; there was no valid argument against its use in the nontuberculous. Tuberculin afforded a means of diagnosis, not alone from observation of the reaction to its injection; the speaker had invariably noted that such patients at once began to put on weight, gaining from three to six pounds the first month of treatment; patients in whom tuberculin treatment was begun so early that diagnosis was questionable, seldom, if ever, failed to be restored to health. Failure in the use of tuberculin might rest on three factors; on the tuberculin itself; on the dose, and on the selection of unfavorable cases. The dose should be regulated, not by the "rule on the bottle" method, but by the immunizing method. The production of antibodies to the tubercle bacilli was accomplished more safely and just as certainly by continued small doses as by large ones. He never went above 0.003 mg. and rarely above 0.002 mg. As long as a patient was steadily improving there was no need to increase the dose. The great danger in using tuberculin was producing too great focal reaction. They had had no means of gauging this—it was suggested that the albumin content of the sputum be adopted for this purpose—the amount of albumin indicating the amount of destruction of lung tissue. Increasing albumin content meant the dose was too large, or it should be discontinued—a decreasing content and no improvement meant the dose was too small. This index of doses must be considered in conjunction with other indications.

Election of Officers.—The following officers were elected for the ensuing year: President, Dr. Richard Weil, of New York; vice-president, Dr. John A. Kolmer, of Philadelphia; treasurer, Dr. Willard J. Stone, of Toledo; secretary, Dr. Martin J. Synnott, 34 South Fullerton Avenue, Montclair, N. J. Members of the council: Dr. Arthur F. Coca, of New York; term expires 1921; Dr. William H. Park, of New York; term expires 1920.

Book Reviews

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

Pulmonary Tuberculosis. By Maurice Fishberg, M. D., Clinical Professor of Tuberculosis, New York University and Bellevue Hospital Medical College; Attending Physician, Montefiore Home and Hospital for Chronic Diseases, New York. Illustrated with 91 Engravings and 18 Plates. Philadelphia and New York: Lea & Febiger, 1916. Pp. 639. (Price, $5.)

This is a work intended to help the general practitioner in his efforts to overcome the tuberculosis scourge, and is based on many years' experience with the related problems in New York city. The author takes pains to show that institutional treatment is not the only effective method of handling the phthisical patient, careful home treatment yielding practically the same results, while less costly to the patient and community. He has also become convinced that incipient tuberculosis is not necessarily curable, while, on the other hand, advanced tuberculosis is not necessarily hopeless. Stress is laid on predisposition as a greater factor in the disease than mere infection with tubercle bacilli, which, after all, produce the disease only in a certain proportion of those infected. In a survey of data on the portals of entry of the infection Fishberg finds no agreement among authorities as to the most common route. In the diagnosis the author warns against giving, in adults, undue weight to a history of exposure to tuberculous infection; in children, however, and especially infants, such a history is of great significance. He places great reliance on "emetic cough" as a diagnostic sign in doubtful cases, after whooping cough has been ruled out. The rectal method of taking the patient's temperature is urged as most trustworthy. In general, the methods of diagnosis of the disease at various ages and under varying conditions are taken up in great detail. In the treatment, while allotting most space to hygienic and dietetic measures, Fishberg likewise discusses extensively the drug treatment, which, he feels, has at times been undeservedly slighted owing to an all pervading therapeutic nihilism. Due attention is paid, e. g., to creosote, ichthyol, arsenic, mercury, codliver oil, etc. The author has little or no faith in tuberculin therapy, and advises the practitioner to abandon it in favor of drugs, by judicious use of which results may be obtained without incurring risk. In hemoptysis he has had satisfactory results from emetine, as originally recommended by French observers. Amyl nitrite in ten to fifteen drop inhalations he has found efficient, but he has discarded adrenaline and believes ergot to be actually harmful. A pleasing feature is the correct rendering of Latin prescriptions, so frequently marred by errors of spelling in textbooks. A special, very complete chapter on artificial pneumothorax is included. On the whole, the practitioner will find the work very helpful. The views expressed reflect recent etiological, pharmacological, and other advances so well that the addition of this work to the already voluminous literature of tuberculosis seems amply justified.

Alcohol. Its Influence on Mind and Body. By Edwin F. Bowers, M. D. New York: Edward J. Clode, 1916.

This work of Doctor Bowers is not a scientific one; it is not a dispassionate examination of alcohol as a medicine or a beverage, but an *ex parte* book, less violent than the customary teetotal attack, but of the same stripe. It is strange that alcohol, man's invariable companion since before the dawn of history, apparently never allows an impartial judgment regarding itself, but seems to stir up as much excitement and intolerance as a topic as it is well known to do when taken in excess as a beverage. The "temperance" writer invariably ignores such plain and unequivocal testimony as that of Dr. Abraham Jacobi, for example, who has often told how alcohol and nothing else saved the lives of numerous children under his care for diphtheria. It is pretty well known now that alcohol is in no sense a stimulant, but an anesthetic of the same physiological kind as ether, although less potent. This fact is triumphantly announced by the total abstainers, as if it settled the alcohol question; it settles nothing, and a genuinely scientific inquiry should be set on foot to ascertain, if possible, why mankind has always demanded a large supply of a powerful narcotic to be constantly within easy reach. Let us grant that alcohol produces deficiency, is guilty, in fact, of all the crimes attributed to it—why has man clung to it and not cast it from him like a venomous reptile?

We have been betrayed into writing an article on alcohol itself, instead of confining ourselves to Doctor Bowers's excellent book; for excellent it is, despite its partisan character. Doctor Bowers says he has weighed alcohol and found it wanting; that it produces deficiency in industry, in health and length of life, in physical, mental, and moral well being. There is a statement to the effect that rarely is there a drunkard who is fond of apples; it is definitely proved, alleges the doctor, that apples are an antidote for the alcoholic craving. We hope no other statement in this book is so baseless as this; the reader has only to remember the popularity of apple toddy in order to splinter the argument. Another mistake, common among prohibitionists, is referring to men who have been induced to stop the use of alcohol as "cured." As one drink will start such a man on a spree, "cured" is not the exact word; he is as much a drunkard as ever—potentially. On the whole, however, the arguments against alcohol are well and temperately stated, and the book is interesting—an important consideration.

The Dream Problem. By Dr. A. E. Maeder, of Zurich. Nervous and Mental Disease Monograph Series, No. 22. New York: Nervous and Mental Disease Publishing Co., 1916. Authorized Translation by Dr. Frank Mead Hallock and Dr. Smith Ely Jelliffe, of New York. Pp. 43.

This little work is one of those classified by the genuine Freudists as *omnino damnanda;* the writer is a follower of Jung, who sees more in a dream than sex matters and retrospection. To him the dream has also a certain prophetic character in that its correct analysis will serve to point out the direction in which the patient must go in order to be cured. Like other works from disciples of either school, this will appear to some readers as an ingenious masterpiece of interpretation, and to others as wild and somewhat degenerate nonsense. To the latter it is a mystery why every slim and upright object, a steeple, a horse's leg, a telegraph pole, must symbolize *membrum virile,* and why the ploughing of a field in a dream means sexual intercourse (page 32). To the Freudist it means nothing else; to the Jung disciple, however, it seems to mean in addition the dreamer's life work. Doctor Maeder gives a full analysis of two dreams from both Freud and Jung viewpoints; as we have always maintained, the theories of these men certainly deserve examination.

Charity Inspector and Social Investigator. Examination Instruction. A Course of Instruction for Candidates for Institutional Inspector, Social Investigator, Inspector State Board of Charities, Charity Application Investigator, etc. 1,500 Official Inspection Questions and 1,000 Questions and Answers, and Specimen Civil Service Examination Questions, etc. By Solomon Hecht, Associate Editor, Civil Service Chronicle, and Julius Hochfelder, LL. M. New York: Civil Service Chronicle, 1916. Pp. 148. (Price, $3.)

This comprehensive handbook, in the guise of lucid question and answer, makes immediately available an encyclopedic knowledge of the best practices in the conduct of public and private charitable institutions. It contains a careful digest of the 500,000 words of text of the New York State laws relating to charities, and reviews the recent notable reforms in the administration of public charity in New York city. To those who have been cognizant of the lax methods which have prevailed in many such institutions, and the hardships, unnecessary disease, and vicious practices which have been the inevitable result of these methods, this book is a welcome statement of present official standards of administration in New York. The Honorable John A. Kingsbury, commissioner of public charities of the city of New York, at the price of intense hostility from the Messrs. Bumble of Headledom, has accomplished notable reforms. By his revision of methods of expenditure of the $10,000,000 spent annually for public charities by New York city, Commissioner Kingsbury has

placed the public heavily in his debt, for he has created an aroused public sentiment concerning the right treatment of dependents and defectives. Incidentally he has caused a demand for exact knowledge of administrative standards and methods, which this handbook supplies in full. Directors of charitable institutions, inspectors, investigators, and other social workers will find the volume to be an invaluable aid, inspiration, and guide. To physicians whose duties bring them into contact with charitable institutions, such as hospitals, asylums, orphanages, and reformatories, in New York or elsewhere, this book is almost essential.

I. K. Therapy (Immunkörper, Immune Substances) in Pulmonary Tuberculosis. With a Summary of Cases and Forty-two Illustrative Charts. By William Barr, M. D., D. Sc. (Glas.), D. P. H. (Camb.), District Tuberculosis Officer for the West Riding of Yorkshire. New York: William Wood & Co., 1916. Pp. 82. (Price, $1.25.)

In the short space of fifty pages the author sets forth succinctly all that is of importance regarding the theory of action of Spengler's Immunkörper, the methods of its administration, its indications and contraindications, the reactions which it may produce, its use in special cases, and the general considerations regarding its probable value and limitations. The results of its administration in a series of forty-seven cases are discussed from several aspects and the general impression is given that the preparation is a valuable adjunct to tuberculosis therapy. The conclusions, however, seem to be based on far too small a series of cases to be regarded as in any way definite, and this fact is well recognized by the author himself. Unlike another small volume recently published on this same subject, the present one is moderate and very conservative, and its author has confined himself to the results of his own experiences, and has refrained from any indulgence in over enthusiasm, although he believes the preparation, I. K., has not received the recognition which is justly due to it.

The National Formulary. Fourth Edition. By Authority of the American Pharmaceutical Association. Prepared by the Committee on National Formulary of the American Pharmaceutical Association. Official from September 1, 1916. Published by the American Pharmaceutical Association, 1916. Pp. xl-394.

The fourth edition of the *National Formulary* occupies a somewhat anomalous position, as it is a legal standard for medicines and preparations described therein, though prepared by a committee of pharmacists for the American Pharmaceutical Association. It differs from the Pharmacopœia in that the latter is the product of a committee appointed by a joint convention of pharmacists and physicians which meets decennially, whereas the *National Formulary* is a product of a committee of the American Pharmaceutical Association alone. The makers of the two official standards, however, work in close cooperation, so that there is no clash of authority, the *National Formulary* practically acting as a supplement to the Pharmacopœia. In the fourth edition, which has just been issued and became a legal standard on September 1st, practically all of the preparations are included which have been dismissed from the Pharmacopœia. As the name indicates, the *National Formulary* is composed mainly of formulas for galenical preparations and serves a valuable purpose in furnishing authoritative standards for such preparations. The present edition goes much further and contains a considerable list of drugs and chemicals for which it provides standards. The work of revision has been done with care and discrimination, and this new edition will prove a valuable addition to the library of every physician. In it will be found formulas for many popular mixtures, many of which are now prescribed under proprietary names. It is to be regretted that the revisers have followed the Pharmacopœia in adopting the word "mil," which is an abbreviation of milliter, as a substitute for the well known term cubic centimetre. It is true that there is a slight difference between the two, but this difference is so slight as to be negligible for all practical purposes. Now that the new term has been adopted in the *British Pharmacopœia*, in the *United States Pharmacopœia*, and in the *National Formulary*, we shall have to think in "mils" instead of cubic centimetres when using the metric system. This adds another to the already numerous difficulties which confront those who wish to popularize the use of the metric system.

Interclinical Notes

Eloise Robinson has a sketch in the *Outlook* for October 11th, called The Hay Field; she overlooks entirely the importance of her subject to a large class in the community who stand in awe of ragweed and goldenrod. We find ourselves introduced, however, to coneflowers and the flaunting fireweed, which sound attractive, and to the "incomparable old gold of brown eyed Susans."

* * *

Frank Marshall White describes in the *Outlook* for October 18th an execution by electricity in Sing Sing prison, and reports an address by Warden Osborne on capital punishment, wherein about all the possible objections are set forth. The duties of the various attendants are described, with the exception of those of the doctors, which makes the cited comment of Doctor Squires, the prison physician, read somewhat oddly: "It's the dirtiest work of the medical profession."

* * *

Schoolitis is the new complaint diagnosed by the family physician on the front cover of *Leslie's* for October 5th, which shows a red headed boy in bed, the young mother devoured with anxiety, and the old and experienced family physician, who promptly diagnoses the character of the trouble.

* * *

The *Nurse* for October exhibits the skill and artistic taste in the editing, which characterize this unusual periodical. The acknowledged wit and humor of Dr. William Brady are enlisted in an article on Man's Archaic Food Tube. Dr. John B. Huber writes on the new treatment of diabetes, a treatment which, the Journal has pointed out, goes back at least as far as Guelpa, who introduced it to the physicians of Paris in 1910. It is a pleasure to meet Dr. S. Adolphus Knopf in these columns; he writes on the open air treatment of tuberculosis. Dr. Thomas Grant Allen is another professional contributor. Papers by nurses and lay writers, with the capable assistance of a skilled photographer, round out an excellent number.

* * *

Albert Jay Nock, in an article on Prohibition in Kansas in the *North American Review* for August, among other good things, wrote the following: "This theory (we must make people good) brings forth two serious practical abuses: First the pernicious confusion of vice with crime and the consequent tendency to erect vice into crime—the confusion of the offence *malum in se*, or that which is opposed to the general reason and conscience of mankind, with the offense *malum prohibitum*, about which the general reason and conscience of mankind is divided. In Kansas, for example, several persons told me that the prohibition law was not invariably enforced, but that it was, on the whole, enforced as well as the laws against murder and burglary!"

* * *

According to the *Survey* for September 23d, in an article by Edith Shatto King, an alumnus of the University of California recently had an attack of pneumonia. He was in a hospital bed for five weeks. When he was convalescent and had paid his bills he found that his illness had cost him, for hospital care, physician's services, and nursing, something over $350. Then he began to make comparisons. For four years, while a student in the University of California, he had paid an infirmary fee of $6 a year, and that infirmary fee had entitled him to all the medical advice, treatment, hospital care, and nursing that he might require, and at no further cost, no matter how protracted or serious his illness. Now, no longer eligible to the privileges of the University infirmary, he had paid out for a single illness money enough to have endowed such infirmary privileges not merely for one person but for three, and not merely for one lifetime but in perpetuity. At present the system provides, in addition to the entrance examinations and dispensary services already described, hospital care, including food, shelter, medical and nursing services; drugs; bacteriological and x ray examinations; and every attention that can be obtained at the best modern hospitals. Every device of diagnosis or treatment that modern medicine has discovered is brought to the aid of the student.

Meetings of Local Medical Societies

MONDAY, *October 23rd.*—Medical Society of the County of New York; Poughkeepsie Academy of Medicine (annual).

TUESDAY, *October 24th.*—New York Psychoanalytic Society; New York Dermatological Society; Metropolitan Medical Society of New York City; Buffalo Academy of Medicine (Section in Pathology); New York Medical Union; New York City Riverside Practitioners' Society; Valentine Mott Medical Society, New York; Washington Heights Medical Society, New York; Woman's Hospital Society, New York; Therapeutic Club.

WEDNESDAY, *October 25th.*—New York Academy of Medicine (Section in Laryngology and Rhinology); New York Surgical Society; New York Society of Internal Medicine; Schenectady Academy of Medicine.

THURSDAY, *October 26th.*—New York Academy of Medicine (Section in Obstetrics and Gynecology); Ex-Interne Society of Seney Hospital, Brooklyn; Hospital Graduates' Club, New York; New York Physicians' Association.

FRIDAY, *October 27th.*—Society of New York German Physicians; New York Clinical Society; Manhattan Medical Society; Society of Alumni of Sloane Hospital for Women; Brooklyn Society of Internal Medicine; Italian Medical Society of New York.

SATURDAY, *October 28th.*—New York Medical and Surgical Society; West End Medical Society; Lenox Medical and Surgical Society.

Official News

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers of the United States Public Health Service for the seven days ending October 11, 1916:

BANKS, C. E., Senior Surgeon. Directed to discontinue operations for the prevention of the spread of poliomyelitis in New York; detailed to attend a meeting of the National Association for the Study and Prevention of Infant Mortality at Milwaukee, Wis., October 19-21, 1916; granted two days' leave of absence on return to station at Milwaukee, Wis.

BROOKS, S. D., Senior Surgeon. Granted seven days' leave of absence from October 9, 1916.

BROWN, B. W., Surgeon. Relieved from duty at New York, N. Y., and ordered to rejoin station at Boston, Mass.; directed to proceed to Petersburg, Va., for duty in connection with the Southern Sociological Congress.

FOSTER, M. H., Surgeon. Ordered to discontinue Service operations in the prevention of the interstate spread of poliomyelitis at Philadelphia, Pa.; directed to rejoin station at Stapleton, N. Y.

FRICKS, L. D., Surgeon. Relieved from duty at Boston, Mass.; directed to rejoin station at Hygienic Laboratory, Washington, D. C.

FROST, W. H., Passed Assistant Surgeon. Directed to represent the Service at the meeting of the American Public Health Association, Cincinnati, Ohio, October 24-27, 1916; ordered to attend the meeting of the National Association for the Study and Prevention of Infant Mortality at Milwaukee, Wis., October 19-21, 1916.

GARDNER, C. H., Surgeon. Relieved from duty at New York, N. Y.; granted twenty days' leave of absence, and directed to rejoin station at Buffalo, N. Y.

GASSAWAY, J. M., Senior Surgeon. Granted ten days' leave of absence on return of Surgeon Oakley to his station.

GILLESPIE, J. M., Passed Assistant Surgeon. Granted one month's leave of absence from October 12, 1916.

GLENNAN, A. H., Assistant Surgeon. Granted one month's leave of absence from October 11, 1916.

GUITERAS, G. M., Surgeon. Directed to proceed from Key West, Fla., to Tampico, Mexico, for investigation of sanitary conditions.

HERRING, R. A., Passed Assistant Surgeon. Relieved from duty at New York, N. Y.; directed to rejoin station at Louisville, Ky.

HETERICK, R. H., Passed Assistant Surgeon. Relieved from duty at New York, N. Y.; directed to rejoin station at Vineyard Haven, Mass.

HUGHES, T. E., Assistant Surgeon. Relieved from duty at Philadelphia, Pa.; directed to proceed to Ellis Island, N. Y., and granted one month and twenty-five days' leave of absence from October 6, 1916.

HURLEY, J. R., Passed Assistant Surgeon. Relieved from duty at Baltimore, Md.; directed to rejoin station at Washington, D. C.; granted fourteen days' leave of absence from October 9, 1916.

IRWIN, FAIRFAX, Senior Surgeon. Directed to represent the Service at the Clinical Congress of Surgeons of North America at Philadelphia, Pa., October 23-28, 1916.

IVEY, R. R., Assistant Surgeon. Relieved from duty at New York, N. Y.; directed to report at headquarters, New York Division, Coast Guard.

JONES, W. M., Assistant Surgeon. Relieved from duty at New York, N. Y., and at San Francisco Marine Hospital; granted twenty-six days' leave of absence from October 5, 1916.

KALLOCH, P. C., Senior Surgeon. Relieved from duty at New York, N. Y.; directed to rejoin station at Portland, Me.

KEARNY, R. A., Passed Assistant Surgeon. Relieved from duty at New York, N. Y.; directed to rejoin station at Boston, Mass.

LOMBARD, M. S., Assistant Surgeon. Relieved from duty at Philadelphia, Pa.; directed to proceed to New Orleans, La., for temporary duty in plague suppressive measures.

OAKLEY, J. H., Surgeon. Relieved from duty at New York, N. Y.; directed to rejoin station at Evansville, Ind.

PAINE, LISTON, Assistant Surgeon. Relieved from duty at New York, N. Y.; directed to proceed to Philadelphia, Pa., for duty at Marcus Hook Quarantine.

PARCHER, GEORGE, Passed Assistant Surgeon. Relieved from duty at New York, N. Y., and at the Delaware Bay and River Quarantine and directed to proceed to the Marine Hospital, San Francisco, Cal., for duty; granted two weeks' leave of absence.

PETTUS, W. J., Surgeon. Relieved from duty at New York, N. Y.; granted fifteen days' leave of absence; directed to rejoin station at Charleston, S. C.

RIDLON, J. R., Passed Assistant Surgeon. Relieved from duty at Baltimore, Md.; directed to report at Bureau for instructions; ordered to proceed to Tampico, Mexico, for investigations of sanitary conditions.

ROBERTS, NORMAN, Surgeon. Granted one month's leave of absence upon return of Passed Assistant Surgeon Parcher to station.

ROBERTSON, H. McG., Surgeon. Directed to represent the Service at the Clinical Congress of Surgeons of North America at Philadelphia, Pa., October 23-28, 1916.

ROBINSON, D. L., Surgeon. Directed to proceed to Rockland, Me., for cooperation in preventing the spread of poliomyelitis from that point in interstate traffic.

SAFFORD, M. V., Assistant Surgeon. Directed to proceed to Providence, R. I., from Boston, Mass., when necessary, to assist in the medical examination of arriving aliens.

SCHERESCHEWSKY, J. W., Surgeon. Directed to represent the Service at the meeting of the American Public Health Association at Cincinnati, Ohio, October 24-27, 1916.

SCHWARTZ, LOUIS, Passed Assistant Surgeon. Relieved from duty in the prevention of spread of poliomyelitis at Philadelphia, and resume immigration duties.

SPENCER, R. R., Assistant Surgeon. Granted twenty-one days' leave of absence from October 23, 1916.

STEVENSON, A. F., Sanitary Chemist. Directed to attend the meeting of International Association of Dairy and Milk Inspectors at Springfield, Mass., October 17-19, 1916.

STONER, J. B., Surgeon. Relieved from duty at New York, N. Y.; granted fifteen days' leave of absence; directed to proceed to Ellis Island, N. Y., for duty.

Stout, J. D., Assistant Surgeon. Relieved from duty at the Marine Hospital, Stapleton, N. Y.; directed to proceed to Charleston, S. C., and report to the commanding officer of the United States cutter *Tampa* for duty; granted three days' leave of absence en route.

Thompson, L. R., Passed Assistant Surgeon. Directed to deliver an address on infantile paralysis at the meeting of the National Funeral Directors' Association at Columbus, Ohio, October 11-13, 1916; granted fourteen days' leave of absence from October 2, 1916.

Trask, J. W., Assistant Surgeon General. Directed to represent the Service at the meeting of the American Public Health Association, at Cincinnati, Ohio, October 24-27, 1916.

Waring, C. H., Assistant Surgeon. Relieved from duty at Baltimore, Md., and directed to report at the Hygienic Laboratory for temporary duty.

Weldon, Lon O., Assistant Surgeon. Relieved from duty at New York, N. Y., and directed to proceed to Ellis Island for duty; granted seven days' leave of absence from October 3, 1916.

Wildman, H. V., Jr., Assistant Surgeon. Relieved from duty on Coast Guard cutter *Seneca* and directed to proceed to Ellis Island, N. Y.

Williams, L. L., Senior Surgeon. Directed to visit San Luis Obispo lighthouse station to investigate typhoid fever.

Williams, L. L., Jr., Assistant Surgeon. Relieved from duty at New York, N. Y., and directed to proceed to Ellis Island for temporary duty; granted seven days' leave of absence.

Wynne, R. E., Assistant Surgeon. Directed to deliver an address on Public Health at Pendleton, S. C., October 24, 1916.

Young, G. B., Surgeon. Directed to proceed to Minneapolis, Minn., to attend the meeting of the Minnesota State Medical Association, October 11-13, 1916.

United States Navy Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Navy for the three weeks ending October 14, 1916:

Allen, D. G., Passed Assistant Surgeon. Ordered to the *Chester* for duty.

Bower, F. T., Assistant Surgeon. Commissioned an assistant surgeon from August 28, 1916.

Cecha, A. H., Assistant Surgeon. Commissioned an assistant surgeon from August 29, 1916.

Crawford, R. L., Assistant Surgeon. Detached from the *Connecticut* and ordered to the *Rhode Island*.

Curl, H. C., Surgeon. Detached from duty as force surgeon, Reserve Force Atlantic Fleet, and ordered to the Marine Barracks, Port Royal, S. C., ordered to duty on the *Michigan*.

Freeman, G. F., Surgeon. Detached from the *Tacoma* and ordered home to await orders.

French, G. R. W., Passed Assistant Surgeon. Detached from the *Maine* and ordered to the Naval Torpedo Station, Newport, R. I.

Garrison, P. E., Passed Assistant Surgeon. Detached from the *Dolphin* and ordered to duty with Expeditionary Forces in Santo Domingo.

Harper, John, Assistant Surgeon. Detached from the *Minnesota* and ordered to duty in connection with fitting out the *Arizona* and duty on board when commissioned.

Huff, E. R., Passed Assistant Surgeon. Detached from the *Scorpion* and ordered home to await orders.

Jacobs, I. W., Assistant Surgeon. Commissioned an assistant surgeon from August 28, 1916.

Langhorne, C. D., Surgeon. Resignation of commission accepted from September 29, 1916.

Leach, Philip, Medical Director. Detached from the Naval Hospital, New York, and ordered to command the Naval Hospital, Boston, Mass.

Lung, G. A., Medical Inspector. Detached from the Naval Torpedo Station, Newport, R. I., and ordered to command the Naval Hospital, New York.

May, H. A., Passed Assistant Surgeon. Detached from the Marine Barracks, Port Royal, S. C., and ordered home to await orders.

Mears, J. B., Passed Assistant Surgeon. Detached from the *Memphis* and ordered to duty with the Expeditionary Force in Santo Domingo.

Murphy, J. A., Surgeon. Detached from the *Michigan* and ordered to duty with the Bureau of Medicine and Surgery, Navy Department, Washington, D. C.

Noble, D. H., Passed Assistant Surgeon. Ordered to the Naval Hospital, Philadelphia, Pa.

Old, E. H. H., Passed Assistant Surgeon. Detached from the Naval Hospital, Washington, D. C., and ordered to the *Solace*.

Plummer, R. W., Surgeon. Ordered to the *Alabama* for duty.

Prioleau, P. F., Assistant Surgeon. Commissioned an assistant surgeon from August 29, 1916.

Smith, C. G., Surgeon. Detached from the Bureau of Medicine and Surgery, Navy Department, and ordered to duty in fitting out the *Arizona* and duty on board when commissioned.

Strine, H. F., Surgeon. Ordered to the Naval Hospital and School, Washington, D. C., September 25, 1916.

Taylor, J. S., Surgeon. Detached from the *Rhode Island* and ordered to the *Connecticut*.

Trible, G. B., Passed Assistant Surgeon. Ordered to the Naval Academy, Annapolis, Md., September 25th.

Triebly, C. E., Surgeon. Detached from the *North Dakota* and ordered to the *Illinois*.

Wilson, George B., Medical Director. Died at Boston, Mass., October 1, 1916.

Wilson, H. D., Surgeon. Ordered home to await orders.

Births, Marriages, and Deaths

Married.

Botbyl-Smith.—In Paterson, N. J., on Wednesday, October 4th, Dr. Burt W. Botbyl and Miss Sarah Holt Smith.

Buckley-Harvey.—In Quincy, Mass., on Thursday, October 5th, Dr. George Ambrose Buckley and Miss Mary Evelyn Harvey.

Freeman-Sprague.—In East Randolph, Vt., on Saturday, September 30th, Dr. Charles West Freeman, of Chicago, Ill., and Miss Ruth Sprague.

Died.

Babcock.—In Morrisville, N. Y., on Thursday, September 28th, Dr. Frankford Duane Babcock, aged sixty-nine years.

Floyd.—In Aurora, Col., on Thursday, September 28th, Dr. Edward A. Floyd, aged eighty-eight years.

Hamilton.—In Wichita, Kan., on Saturday, September 30th, Dr. Ernest E. Hamilton, of Wichita, Kan., aged sixty-one years.

Haney.—In Dalton, Ohio, on Monday, September 25th, Dr. Josiah C. Haney, aged fifty-two years.

Hudgins.—In Olive Hill, Ky., on Thursday, September 28th, Dr. Cecil Hudgins, aged fifty-seven years.

Hudson.—In Princeton, Ind., on Friday, September 22nd, Dr. Oliver L. Hudson, aged eighty-three years.

Hunt.—In Washington, D. C., on Monday, October 9th, Dr. Arthur L. Hunt, aged thirty-nine years.

Kilborn.—In New York Mills, N. Y., on Monday, October 2nd, Dr. Henry F. Kilborn, aged seventy-two years.

King.—In Richmond, Va., on Saturday, September 30th, Dr. Lawrence Y. King, aged forty-five years.

McMeekin.—In Saginaw, Mich., on Tuesday, October 3rd, Dr. James W. McMeekin, aged fifty-seven years.

Miller.—In Hagerstown, Md., on Thursday, October 5th, Dr. William P. Miller, aged forty-six years.

Sauermann.—In St. Louis, Mo., on Tuesday, October 3rd, Dr. Hans H. Sauermann, aged fifty-five years.

Stiles.—In Philadelphia, Pa., on Saturday, October 7th, Dr. William Stiles, aged seventy-four years.

Wilcox.—In Smithfield, Ky., on Monday, October 2nd, Dr. Josiah L. Wilcox, aged eighty years.

Wilson.—In Chelsea, Mass., on Sunday, October 1st, Captain George B. Wilson, Medical Director of United States Naval Hospital in Chelsea, aged fifty-three years.

Woods.—In Philadelphia, Pa., on Friday, October 13th, Dr. Matthew Woods, aged sixty-eight years.

ANESTHESIA REVIEWED.

BY JAMES T. GWATHMEY, M. D.,

New York.

PART I.

Momentous advances have been made in the study of anesthesia during the past few years, especially with reference to the physiological action of the different anesthetic agents, and the adaptation of the agents and methods of administration to the patient or operative procedure.

Despite these advances, there is still a disposition on the part of some distinguished surgeons to minimize the importance of varying the agent and the method under different surgical circumstances. Hence, in some of the largest and most efficient clinics, such as those of the Mayos and Crile, nurse anesthetists are still employed—which means that one method is used in all cases.

The following review shows, to my mind, that the results and statistics of these clinics, excellent as they are, would be greatly enhanced by the adoption of the more scientific and flexible use of anesthesia, namely, by suiting the agent and the method to the individual patient and procedure.

My own conclusions in this regard may be stated briefly as follows:

1. There should be, connected with the clinic, one or more persons whose efforts are limited to the administration of anesthetics.

2. Such persons should perfect themselves in the ability to maintain, with the chosen method, the *lightest surgical* anesthesia consistent with the surgeon's best work.

3. The surgeon should let the anesthetist *alone*.

4. Inasmuch as anesthesia is still in an elementary stage of its evolution, the supervising anesthetist should be a *physician specially trained in this work*.

The following review, it seems to me, bears out these conclusions.

CLOSED ETHER AND A COLOR SIGN.

Bryant and Henderson (1), in a paper with this title, express the view that rebreathing is preventive of shock. We are not warranted in accepting this theory as a fact. They are right in stating that gas pains may follow the ether open drop method, but this is true only under certain conditions. For instance, if no preliminary medication is given, if unusual care is exercised to prevent the patient from being anesthetized too long, and if the operation is started as soon as the patient is unconscious, but not anesthetized, there might be hyperpnea followed by acapnia, and probably by gas pains and shock afterward; but under similar conditions this might also occur with the closed method. We deny that depression of the circulation and respiration, postoperative nausea, vomiting, intestinal paresis, and gas pains are incidental to etherization by open methods, unless by open methods the drop method is meant. The many thousands of cases anesthetized by the endotracheal and endopharyngeal method, in which method rebreathing is practically eliminated, and in which none of these features occur, would seem to disprove the acapnic theory; as would also the many thousands of cases anesthetized with the semiopen vapor mask method, in which the pulse and respiration are normal throughout. A more accurate conclusion would be, that given a patient properly prepared, ether may be used indifferently by either the open or the closed *vapor* methods. The principal point of the paper, "Keep the patient pink," is a life saving suggestion.

The statement that "to see closed ether given as a routine, one must go to France or Denmark," is a delightful provincialism, which is paralleled to a degree by a contemporary (2), who states that "ether vapor discharged into a large rubber bag is not generally used in administering ether vapor." The fact is that "discharging ether vapor into a large rubber bag" is one of the very best methods of administering ether. It was introduced by Woolsey, in 1912, and it has been used by the writer and others constantly ever since. It compares favorably with nitrous oxide and oxygen, and is probably safer. Falk (3) reported 800 cases by this method in 1913, and it is used daily in the French (Manhattan) and the Jewish (Brooklyn) Hospitals of this city.

This last cited contemporary, in reviewing the subject of warming ether vapor, employed methods similar to those of Seelig, whom he quotes in his investigations. Among other conclusions, they state that "the warming of ether vapor, however administered, is accomplished in the mouth, pharynx, trachea, and primary bronchi." It may be assumed from this that they had as indifferent success as Seelig (4) had in heating ether vapors. Seelig stated that, "even if we heat it (ether vapor) to a considerable degree, the gas will lose practically all its heat before we can deliver it to the patient." Again, he

states, "the warmed ether vapor will not stay warmed unless it is held under pressure." It has been shown (5) that ether vapor can be delivered to the patient at any desired degree of heat, and regardless of pressure.

Both Davis (11), of Baltimore, and Nagel, of Montreal, have shown that the temperature is very greatly reduced by the "drop method" of ether. Davis has shown that it is not reduced when the ether is properly given. In the majority of cases reduction of temperature may not mean anything, as the temperature returns to normal a few hours after the patient is restored to bed. In certain borderline cases it may be the dividing point between life and death. The more "open" the method, the more dangerous becomes the "drop" ether, as the amount is necessarily increased, and the full toxic effect of the drug is reached in order to maintain anesthesia. With a semiopen or closed method, both the amount and the toxicity are immediately decreased.

RELATIVE VALUES OF SO CALLED WARMED AND UNWARMED ETHER VAPOR.

Seelig, Boothby, Cotton (6), and others held that it was impossible to deliver warm ether vapor to a patient. They should publicly acknowledge their error. This paper opens up the whole question of the value of warmed ether vapor. The warming of ether vapor is a demonstrated fact, and is no longer open to discussion. The question of its usefulness, however, is still disputed. We may state briefly that the value of warmed ether vapor is based upon, 1, theory; 2, laboratory experimentation; and, 3, clinical experience.

1. *Theory.* The theory of warmed anesthetics is based upon the presumption that inhalation anesthetics increase in value as their specific gravity decreases. The following table of anesthetics, arranged according to their specific gravity, falls in with the generally accepted statistics regarding their comparative safety, and seems to warrant the theory.

Specific gravity (after Baskerville). The specific gravities of the vapors, compared with air—one volume at 0° C. and 760 mm. barometric pressure:

Oxygen	1.105;
Nitrous oxide	1.52;
Ethyl chloride	2.22;
Ethyl ether	2.56;
Chloroform	4.21.

By heating chloroform, for instance, and giving it by the closed method, as will be shown later, it is probably equally safe and acts in exactly the same way as oxygen and nitrous oxide; which proves, in a measure, our contention that all anesthetics are increased in value when heated to the temperature of the blood.

LABORATORY EXPERIMENTATION.

As far back as 1873 or 1874, Clover found that by warming an anesthetic by rebreathing, the anesthetic was increased in value and safety. In 1905, the writer took up the different anesthetics, in regard to temperature, experimenting upon them as to safety, maintenance of body temperature, recovery from anesthetic and aftereffects. It was found, after using thirty-three animals, that it required over twenty minutes on an average to kill an animal with chloroform at 100° F. At room temperature, it required only a little over six minutes. It would thus seem that chloroform at blood temperature is three times as safe as chloroform at room temperature.

The same holds true with nitrous oxide and oxygen. It is almost impossible to kill an animal with warm nitrous oxide and oxygen. Using the same technic, it requires only nine minutes to kill an animal with nitrous oxide and oxygen at room temperature, but eighteen minutes with the gases heated to 98° F. The same holds true with ether; it takes much longer to kill an animal with warm ether than it does with cold. These are end results, and have never been successfully controverted. Certain surgeons and anesthetists held for a time that it was practically impossible to heat ether to body temperature; but this is disproved by the daily use in many clinics of ether heated and remaining heated until inhaled by the patient.

Body temperature. Davis, of Baltimore, has proved that patients lose only 0.29° F. with warmed ether vapor, against a loss of 1.02° F. with the open drop method. The temperature was taken per rectum immediately before starting and immediately after the removal of the anesthetic. The contrast in the general appearance of a patient anesthetized by warmed ether vapor, and another by the open drop method, is all in favor of the patient under the warmed ether vapor. With infants and those in very delicate health, why should not the ether be warmed as well as anything else required for their general health?

CLINICAL EXPERIENCE.

Only those who have actually used both warmed ether vapor and vapors at room temperature are competent to judge of this matter. Would-be critics, who view the question from a theoretical standpoint, and who have never used ether except at room temperature, have no voice in the matter. The fact that professional anesthetists, men who make their living by the administration of anesthetics, such as Teter, of Cleveland, Coburn and Hunt, of New York city, Ansell Cain, of New Orleans, McCormack, of Akron, myself, and many other professional anesthetists have tried both methods and are firmly convinced of their value, should certainly have more weight than that other equally good professional anesthetists who have been swayed by theoretical views, and who have not put the matter to clinical test, should disagree. The further fact that anesthesias are safer and easier to maintain in the summer time than in the winter, and much safer in southern than in northern climates, is borne out by the observations of many competent anesthetists.

PRELIMINARY MEDICATION.

Up to recent times, the value of preliminary medication has been more a matter of opinion than of fact. This refers especially to morphine. In a recent most valuable paper, Benjamin Franklin Davis (7), of Chicago, states: "Morphine alone, preceding local anesthesia, adds nothing to the efficiency of the anesthetic. . . . It makes the patient 'dopy,'

and hence deprives the operator of the cooperation of the patient, which at times may be valuable." Bodine, in a personal communication, agrees with Davis that morphine adds nothing to the efficiency of the anesthetic; but states that he gives it in order to "get the *cooperation* of the patient, which is most valuable."

From a broad viewpoint, Bodine is right. A patient is certainly more tractable under morphine than without it. Davis further states, "the preoperative use of morphine should be abandoned, because of the disadvantages of imposing one powerful depressant of the medullary centres, namely, morphine, upon another—namely, ether." The writer has always looked upon *ether* as one of the most stimulating drugs in the whole pharmacopœia. It stimulates respiration, circulation, and every gland and organ of the body. It may be that Davis refers to ether used improperly by the drop method. If, however, it can be proved that morphine is responsible for the small number of cases of postoperative nausea and vomiting, it might be well to discard morphine and employ some other preliminary medication.

Proper preliminary medication renders any anesthetic safer, and eliminates largely the possibility of reflex inhibition, during either local or inhalation anesthesia; it also renders the induction smoother, and the use of holding straps unnecessary. To withhold this, or some similar preliminary, and allow a patient to come to the operating room with all senses alert, usually means an ineffaceable scar on the memory of the patient. It is much easier to maintain an even plane of anesthesia with preliminary medication; and for this reason postoperative vomiting is decreased. Certain preliminaries seem to render easier the postoperative voiding of urine. Preliminary medication is probably employed in over sixty per cent. of the hospitals in the United States, and will be increasingly used as the facts upon which its use is based become better known.

In order to determine whether preliminary medication increases the *margin of safety* of ether anesthesia, experiments have recently been completed in the laboratory of the New York University and Bellevue Hospital Medical College, the detail work being carried out by Dr. E. J. Pellini and the writer. The full report of these observations will soon appear.

Experiments were carried out as follows: A number of animals received each an injection of morphine sulphate for the purpose of rendering them more tractable. Ten minutes later 0.5 c. c. of paraldehyde and one c. c. of potassium bromide per kgm. weight of animal in enough water to make a complete solution, were given by stomach tube. This was allowed to act for about forty-five minutes, after which the animal was placed on the table and anesthetized by the intravenous injection of seven per cent. ether in saline. The time and the quantity of ether solution used was noted *when complete anesthesia* had taken place, and *again when respiratory paralysis occurred*. The animal was then resuscitated by artificial respiration. A period varying from four to seven days or over was allowed for recovery. After this rest the *experi-*

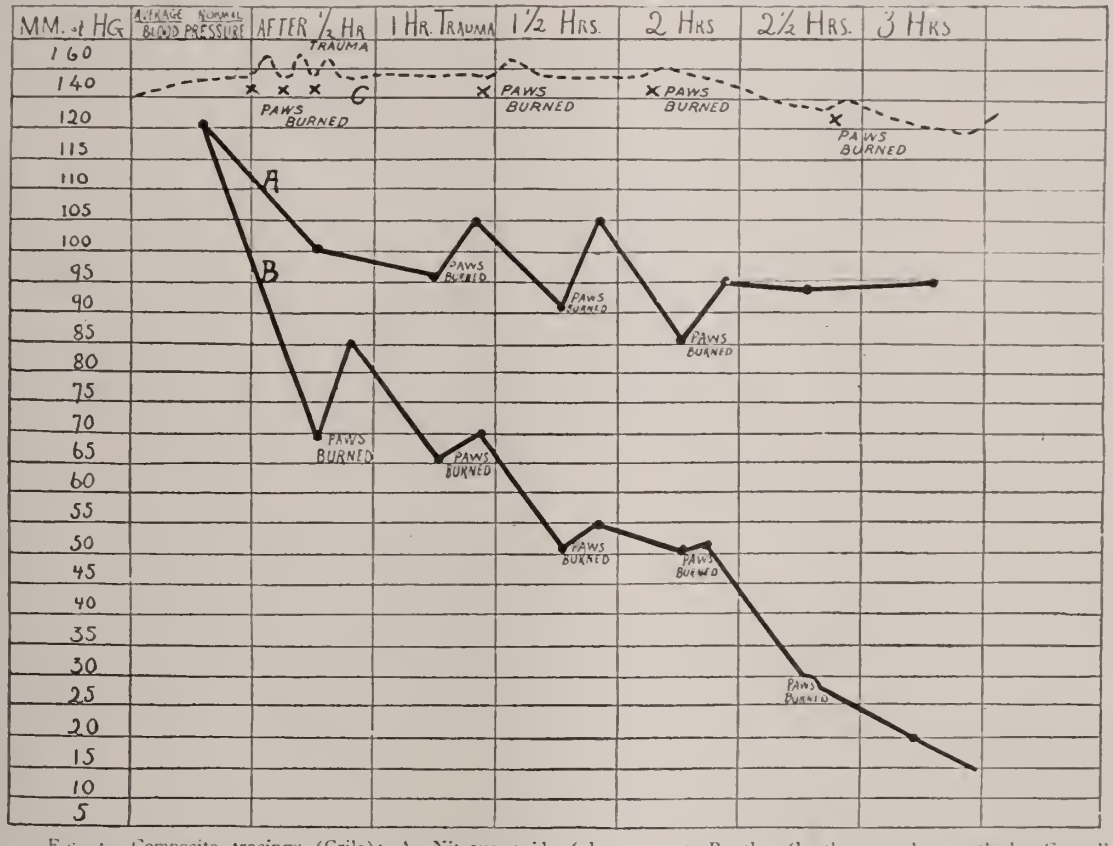

FIG. 1.—Composite tracings (Crile): A, Nitrous oxide (plus oxygen); B, ether (by the open drop method). Connell and Gwathmey: C, Ether by the endopharyngeal method.

ment was repeated with and without the preliminary medication, except for the morphine.

The following is a protocol showing especially the "margin of safety":

DOG NO. 20.—WEIGHT, 13 KILO.

Without Preliminary Medication.

June 15, 1915.

10.30 a. m.	0.5 c. c. of 2 per cent. morphine solution.
11.34	Started intravenous ether administration.
11.38½	*Complete anesthesia, using 134 c. c.* ether solution.
11.42	Respiratory failure; *required only 99 c. c. more ether solution.*

With Preliminary Medication.

Sept. 7, 1915.

2.50 p. m.	0.5 c. c. of 2 per cent. morphine solution.
3.10	6.05 c. c. paraldehyde and 13.0 grams potassium bromide.
3.59	Started intravenous ether administration.
4.01⅔	Complete anesthesia, using *87 c. c. ether solution.*
4.09⅓	Respiratory failure, required *245 c. c. more ether solution.*

From the foregoing we may note:

1. Anesthesia comes on sooner and less ether solution is used after the administration of preliminary medication.

2. The margin between complete anesthesia and respiratory failure is lengthened with preliminary medication, making anesthesia a safer procedure; in other words, "the margin of safety" is increased.

In every instance the animal was anesthetized more easily and with less excitement when preliminary medication was employed.

Preliminary to surgical operation, or as a hypnotic to replace or to assist morphine, this combination can be used with confidence; it has been most satisfactorily used in over 200 cases. When for any reason ether is contraindicated, it can be used as a preliminary to nitrous oxide and oxygen.

With the patient in the Sims position, give per rectum:

℞ Paraldehyde, Potassii bromidi, ... āā ʒi vel ij;
Aquæ q. s. ad ..... ʒiv.
M. Sig. Give thirty minutes before operation.

Crile (8) has demonstrated that when the administration of morphine precedes the induction of anesthesia, the acidity of the blood is less than in anesthetized animals which have not received this preliminary dose. Neither did the morphine when thus given interfere with the return of the blood to its normal alkalinity. If, however, morphine was given *after* acidity had been produced by the anesthetic, it delayed the time of neutralization; and if given in large doses it prevented the animal from overcoming the acidosis. It seems, therefore, that morphine, as a regulator of acidosis, should always be given before, instead of after operation.

Those who have given preliminary medication a thorough clinical test are firmly convinced of its value from both a psychic and a practical standpoint. The new preliminary, paraldehyde and bromide of potassium, admits of many variations, and should have a thorough trial. For instance, bromide of potassium, one to two drams, may be given in a quart of water, per rectum, the night before the operation. The paraldehyde may be given alone or in combination with morphine, one half to three quarters of an hour before the operation. Either drug may be given alone or in combination with the other. All authorities are agreed that paraldehyde and potassium bromide are among the safe drugs of the pharmacopœia.

LIGHT ANESTHESIA.

Gatch has shown very conclusively that, generally speaking, light anesthesia is safer and better in every way than deep anesthesia. McKesson (9) seems to bear out this theory in his study of blood pressure. He states that "any influence which reduces the pulse impact or pulse pressure, even though an increased pulse rate maintains an equivalent or greater output of blood, is a cause of arterial dilatation, or congestion, which may be of such general distribution as to be the cause of shock. This is one of the results of pushing an anesthetic to deep relaxation, which reduces the pulse pressure in the same way and at the same time that the skeletal muscle is relaxed, with a difference only in degree." The writer wishes to add his opinion that the lightest possible anesthetic consistent with the surgeon's best work, is the safest for the patient. The dangers of a light anesthesia are, first, the possibility of the surgeon beginning his work before the patient is fully anesthetized; and, second, reflex inhibition. This latter event is hardly possible under a good ether or nitrous oxide and oxygen anesthesia.

NITROUS OXIDE VERSUS ETHER ANESTHESIA.

A paper that possibly had more to do with the general acceptance of nitrous oxide and oxygen than any other, was published by Crile (10) in January, 1910. The writer, among others, was influenced by the accompanying chart (page 827). As his views have changed considerably regarding the comparative value of nitrous oxide and ether, it is high time that the results of the joint work of Connell and himself should be published.

The composite tracings in black (see chart) showed that "an animal under nitrous oxide anesthesia endured shock producing trauma better than an animal under *ether* anesthesia." Crile at that time ignored all other methods of giving ether except the "drop method." This experiment of Crile's was paralleled by Karl Connell, assisted by the writer, in the medical college laboratories of Columbia University, but with this notable exception; the ether was given pharyngeally by a vapor method in which the quantity of ether and the volume of air was known at all times. The dotted line tracing shows the result. Bearing in mind the fact that the ether in Crile's experiment was given by an expert, and by the "drop method," the caption for this chart as it now stands should read: An Indictment of the "Open Drop" Ether Method; or Ether, when Properly Given, is as Safe an Anesthetic as Nitrous Oxide.[1]

[1] This chart was presented at the annual meeting of the American Association of Anesthetists at Detroit, in the discussion of Doctor Crile's paper on An Experimental Research Into Nitrous Oxide and Ether. Dr. Crile stated that, in addition to burning the dog's paws, the abdomen was opened and the peritoneum scraped in order to produce shock. In the article he does not state that this was done. The tracings, therefore, are not comparable. The chart does show very conclusively that under ordinary trauma the blood pressure is fully sustained when ether is given properly. In the writer's opinion, the results of all comparisons of nitrous oxide and oxygen to ether given by the drop method are worthless, inasmuch as the "drop ether" is not a scientific method.

If all of Crile's experiments with ether mean that the "drop method" alone was used in comparison with nitrous oxide anesthesia, then all of his deductions are erroneous. *Animals under ether, properly given, stand shock as well as those under nitrous oxide anesthesia.*

PART II; BEVAN'S THEORIES.

A paper by Bevan (12), comparing the different anesthetics and methods in common use, is full of misinformation, but is so excellent in arrangement that I propose to close this review by patterning my own criticisms according to his plan.

Bevan's paper considers all anesthetics from the following standpoints: First, safety; second, comfort; third, efficiency; fourth, control—avoiding anesthetics which cannot be withdrawn at the first appearance of danger; fifth, simplicity and general adaptability of method; sixth, aftereffects on blood, tissue, and viscera; seventh, complications—vomiting, etc.; eighth, effect on immunity against pus organisms, pneumococci, etc.

While following the outline of this paper as closely as practicable, it will be impossible for us to consider certain agents alone, as Bevan has done, for the reason that American and European statistics, as well as a knowledge of the physiology of the drugs under consideration, teach us that anesthetics in combination and sequence are safer than any single agent used alone. For instance, nitrous oxide should never be used alone; oxygen should always be associated with it, and in many cases ether makes it still safer; chloroform, too, is much safer when used with ether and oxygen. All anesthetics are increased in value by the use of oxygen, rebreathing, moisture, and warmth.

The views of Bevan are given in the left column of the parallel; those of the writer in the right column.

CHLOROFORM BY INHALATION.

Open drop method (Bevan).	*Closed method with rebreathing, preferably by the Roth-Drager apparatus (Gwathmey).*
1. Safety.	
The most dangerous of all inhalation anesthetics. Deaths from one in 1,000 to one in 3,000 on the operating table.	One of the safest of all inhalation anesthetics. Death on the table almost impossible.
2. Comfort.	
A most agreeable anesthetic to the patient.	Same.
3. Efficiency.	
The most efficient anesthetic. Anesthesia and relaxation profound and complete.	Same.
4. Control.	
The anesthetic can at once be stopped on the appearance of danger signals, but the chloroform already in the system cannot be rapidly eliminated, and the effects persist for a considerable period. The margin between the required anesthetic dose and the toxic dose is too narrow for safety.	The anesthetic can at once be stopped on the appearance of danger signals, and when mask is removed the chloroform in the system is rapidly eliminated, the patient awakening immediately as from a good nitrous oxide-oxygen anesthesia. The margin between the required anesthetic dose and the toxic dose, when given in this way, is extremely wide.
5. Simplicity and General Adaptability.	
All that could be desired.	Same.
6. Aftereffects on Blood, Tissues, and Viscera.	
Reduces hemoglobin. Produces often what is now generally recognized as late chloroform poisoning with fatty degeneration of liver, kidneys, and muscle tissue, which is usually fatal.	*Late* chloroform poisoning, fatty degeneration of organs, reduced hemoglobin, etc., do *not* occur when given as outlined above.
7. Complications.	
Vomiting in about one third of the cases. Lung complications and nephritis in a small percentage.	Lung complications, nephritis, vomiting, rare if ever.
8. Effects on Immunity.	
Reduces resistance against pus organisms, pneumococcus, etc.	Resistance unimpaired.
Conclusions.	
Because of its efficiency, comfort, and simplicity, it has probably been employed more generally the world over than any other anesthetic, possibly more than all other anesthetics combined. And yet the time has come when chloroform, in spite of its many advantages, should be absolutely and finally discarded because of the huge mortality attending its use, both on the operating table and the late chloroform deaths, and because we have for all classes of surgical cases efficient and much safer agents. It is possible that in military surgery chloroform may still find a legitimate place.	Chloroform, even with this apparatus, is rarely used throughout, being usually combined with ether as required. Chloroform should also be used warmed and with oxygen as a preliminary to ether vapor anesthesia. It should never be used in routine practice by the drop method as a terminal anesthetic. With some patients (obese alcoholics), and for short operations, it is one of the safest anesthetics. It should also be used with patients who have suffered severely from previous ether administrations.

ETHER BY INHALATION.

Open drop method (Bevan).	*Ether by vapor method, with definite quantities of air and oxygen—open or closed method (Gwathmey).*
1. Safety.	
The safest anesthetic agent known for prolonged anesthesia. Deaths from one in 5,000 to one in 10,000.	Much safer than the open drop.
2. Comfort.	
Not an agreeable anesthetic to take, especially by the closed methods; much more agreeable in expert hands by the open drop methods.	Most agreeable by either open or closed method—essence of orange-ether sequence.
3. Efficiency.	
Very efficient; complete anesthesia and relaxation can be obtained.	More efficient and more complete anesthesia and relaxation than the "open drop."
4. Control.	
The anesthetic can be stopped on danger signals, and the agent fairly rapidly eliminated, if necessary, under artificial respiration. The margin of safety between the anesthetic dose and the toxic dose is wide.	Same.
5. Simplicity.	
Simplicity and general adaptability by the open drop method is all that could be desired.	Simpler and better adapted to general use than the drop ether.

6. Aftereffects on Blood, Tissues, and Viscera.

Reduces hemoglobin, slightly increases coagulation of the blood, and produces few if any cases of injury to the liver, kidneys, and muscle tissues such as occur from chloroform.	Same, except reduction of hemoglobin a question.

7. Complications.

Vomiting in from thirty to forty per cent. of cases. Lung complications and nephritis in a small percentage of cases.	Vomiting in only ten to fifteen per cent. of cases. Surgical complications and nephritis same.

8. Effects on Immunity.

Reduces slightly resistance against pus organisms and pneumococci, etc.	*No loss of resistance* against pus organisms.

Conclusions.

Ether by the open drop method is the safest general anesthetic known for producing prolonged anesthesia. It should be today the standard anesthetic in the surgical clinic. The discomfort of ether anesthesia when properly given by the open drop method by an expert can usually be practically eliminated. In the few cases in which the repugnance to ether is great, the sequence of gas-ether can be employed. The closed method of giving ether is not so satisfactory or so safe as the open drop method. Complicated apparatus to control the percentage of ether and to warm ether possess no advantages over the simple drop method and should be discarded. The giving of ether by the drop method is an art which must be acquired under the instruction of an expert.	Ether by the open drop method is a crude, unscientific method, and should *never* be used in this way except as a *sequence* or as a *preliminary* to some other anesthetic or method. The open drop method is a negative proposition, depending for its safety upon the fact that the gauze on the mask freezes to such an extent that an overdose is prevented. Open drop and the gas-ether sequence are both pioneer methods that have long outworn their usefulness. Some patients are safer and better with the open method, others with the closed method. No human hand can approximate the even ether vapor given from a compressed air machine or oxygen tank.

(To be concluded.)

THE SOURCES OF ERRORS IN DIAGNOSIS.

An Analytic Retrospect Based Upon a Quarter Century's Experience,

By Edward C. Hill, M. D.,
Denver.

My work as a medical man has been chiefly concerned with diagnosis in association with other physicians and surgeons, and I have committed and observed numerous mistakes in diagnosis, nearly all of which might have been avoided by taking time and giving more attention to the details of each case. In the enforced hurry of college clinics and hospital wards "guess and guess again" is, in the nature of things, more commonly practised than with our private patients. For convenience of presentation, I shall take up the principal causes of diagnostic errors under a dozen different headings.

Mistaking symptoms for diseases. In the prepathological period the rule was to treat symptoms rather than diseases. Those were the days of winter cough, spring fever, and summer diarrhea; of black water, pink eye, and green sickness, not to mention "blue balls" and "yaller janders." Symptomatic treatment should be always regarded as merely a temporary palliative measure. In my little book, *Pain and Its Indications,* I have differentiated 175 separate and distinct causes of headache, scarcely any two of which should be treated just alike. So for insomnia we may give trional, veronal, luminal, sulphonal, and damnitall, world without end, but a cure of the condition is not to be expected along this line. Cough can arise all the way from wax in the ear to an incompetent heart, as well as from any affection of the respiratory tract.

The stomach is a central signal station for the autonomic nervous system, and dyspepsia, when not psychic in origin, or dependent upon ulcer, cancer, or obstructive adhesions, is nearly always a reflex from a diseased appendix or gallbladder. No two conditions are more liable to be confounded clinically than hyperchlorhydria and the hyperacidity due to fermentation resulting from deficiency of hydrochloric acid; and only a chemical analysis of the gastric contents following a test meal can decide the diagnosis and proper treatment. Albuminuria accompanies a hundred different conditions (hemic, toxic, nervous, circulatory, adventitious, postural, etc.), beside organic affections of the kidneys, in the diagnosis of which, indeed, the blood pressure and the eye grounds are often of equal importance with the urinary analysis. I remember distinctly the case of a young man who, twenty-five years ago, was rejected for life insurance in an old line company because of a trace of albumin due to gonorrhea, from which he was then suffering. The good old medical examiner has long since crossed over the range, while the rejected applicant is hale, happy, and prosperous.

Mistaking effects for causes. Nowhere else than in medical diagnosis is it easier to put the cart before the horse. The different forms of anemia, for instance, are practically always secondary to some infection—pyorrhœa alveolaris may cause pernicious anemia—loss of blood, (hemorrhoids, menorrhagia), intestinal stasis, chlorosis, or conditions of malnutrition; and while iron and arsenic are of great service in the treatment of anemia, the cure must be sought further back than in the blood. Dropsy, by the laity, is commonly considered a disease, but is in reality, in the great majority of instances, a sign of disease of the heart, kidneys, or liver. Pleurisy is practically always a complication of pneumonia (which it often obscures), tuberculosis (usually latent), or some other general infection.

We shall not soon forget that beautiful nebular hypothesis which Alexander Haig constructed some twenty years ago, with uric acid as the central sun. Unfortunately for this attractive theory it has been demonstrated, by conclusive clinical and laboratory tests, that (except perhaps in gout) excess of uric acid is always a secondary condition, dependent upon a rapid or excessive breaking down of nucleins (most marked in leucemia) and purin bodies in the food or the tissues (fevers and inflammations). Time and again have I seen the daily quantity of uric acid in the urine diminish to normal with improvement of oxidation through measures directed

to the heart and the blood. A case of this nature was seen with Dr. Melville Black, the daily output of uric acid being more than doubled and the patient unable to see to read, made a perfect recovery under a program of elimination and circulatory tonic treatment.

Overlooking the focus of infection. The great majority of diseases which physicians and surgeons are called upon to treat, are of infectious origin, and only by finding and removing sources of bacterial poisoning can we hope to aid nature in achieving a permanent cure. We are coming more and more to realize the etiological importance of infectious foci, as, for instance, the gums, teeth, and tonsils in arthritis (even of the feet), and Dana has lately reported cases showing very painful protracted periosteal lesions due to metastatic infections. As maintained by Dr. William C. K. Berlin, of this city, nephritis is probably nearly always a result of bacteriemia or of chronic irritation by the toxins of attenuated or destroyed bacteria—the so called latent infections of Adami. Opie and Adami have taught us how latent infections, particularly colon toxemia from the bowels and the streptococcal poison of pyorrhœa alveolaris, give rise to cirrhosis of the liver (favored by alcohol or chloroform) and to pernicious anemia (hypochlorhydria predisposing by lessening antisepsis).

Many obscure, painful, and debilitating conditions are the result of continual poisoning of the blood and nerves from pockets of pus in the glands (tonsils, prostate) or in bony cavities (antrum disease especially). In the acute suppurative otitis media of infants, a febrile temperature may be the sole manifestation, and in over half of these cases there is no indication of pain on the part of the little patient. An interesting subject of study in the category of infection was seen two years ago in consultation with Dr. F. G. McElveen. The patient, a plumber, had been confined to his room for several weeks because of a painful partial paralysis of the lower limbs, diagnosed by a neurologist a few days before, as due to myelitis, with fatal prognosis. On entering this patient's room we at once noticed an offensive odor, which we traced to his tonsils, an exceptionally foul and ragged pair. We concluded that the patient was suffering from multiple neuritis due to septic infection from the tonsillar region. Tonsillectomy was performed, and the man was well and working at his trade in less than three months.

Disregarding diet and habits. Whether or not we agree with the Teutonic proverb, *Man ist was er isst*, the evil effects of improper diet and intemperate habits are universally acknowledged. Witness the gastritis, neuritis, and hepatic cirrhosis of chronic alcoholism, and the hyperchlorhydria, irritable heart, and vasomotor depression of habitual nicotinism. The etiological influence of proteins is as evident in nephritis and arteriosclerosis, as is that of carbohydrates in diabetes mellitus. Skin diseases are particularly related to errors in diet, as Bulkley has well shown, and I recall the case of a man who had suffered several winters with an aggravated type of eczema of the hands, cured at once and permanently by giving up coffee on the advice of Dr. J. N. Hall. Urinary troubles may be made either better or worse by the amount of water ingested. Illustrative of this fact, I may cite the case of a tramway motorman who came to me with the self made diagnosis of stone in the bladder, because forsooth he had to hurry to empty his viscus at the end of each run. Upon examining his urine, I found it actually to contain about four times the usual amount of sodium chloride, and this was due to salt addiction, which led to the drinking of a profuse quantity of water. Upon correcting this bad habit, he promptly recovered.

A very striking example of the relation of food to stomach disorders was that of a young man who was sent to Dr. Joseph Cuneo from the western part of the State, with the tentative diagnosis of gastric cancer based upon pain, vomiting, loss of at least twenty-five pounds in weight, and a lack of free hydrochloric acid with the presence of much lactic acid in the siphoned gastric juice. While questioning and examining the patient, we heard a rustling sound, which we ascertained came from a paper bag of candy in the young man's pocket. He was, in short, a candy "fiend," eating confectionery continually. He was at once deprived of sweets in general, his abdominal symptoms subsided, and within two months he had more than regained his former weight and strength.

During the year 1907 there were in the registration area of the United States fifty-eight deaths attributed to "ptomaine poisoning." In the same year in India 24,000 people were killed by poisonous serpents. At present, in this country, according to government statistics, about twenty-five persons lose their lives each week because of gasoline burns or explosions. "Ptomaine poisoning," like "rheumatism," is nearly always something else. In fact, the term itself is mainly a misnomer, for which "bacterial food poisoning" should be substituted. The causative bacteria belong to but a few groups, including as most important Bacillus proteus (putrefied meat or fish, potato salad), Bacillus paratyphosus and Bacillus enteritidis (diseased animals), Bacillus coli, and Bacillus botulinus, which causes the very fatal but extremely rare nervous type of anaerobic food poisoning (sausages, hams).

Most cases of so called ptomaine poisoning are either acute indigestion from excess of food or an incompatible combination of foods, or else some more or less obscure surgical condition, such as perforating duodenal ulcer or mesenteric thrombosis. To illustrate, a hotel employee, soon after eating a late supper of oysters at a well known Denver fish and oyster house, was taken very ill with abdominal pain, vomiting, purging, and collapse, and died within a few hours. The physician who attended him was ready to sign the certificate of death as being due to "ptomaine poisoning." A toxicological analysis of the vomit, made by myself, proved negative. At Coroner Jaeger's direction the body was submitted to autopsy, skillfully done by Dr. Helen Craig. This autopsy revealed serious syphilitic changes in the heart and large bloodvessels, and particularly multiple tuberculous ulcers of the small intestine. One of these ulcers had perforated the bowel and excited all the symptoms wrongly diagnosed as "ptomaine poisoning." If a necropsy had not been

performed, and the newspapers had given the matter the usual sensational publicity, we can easily deduce what a rank injustice would have been perpetrated upon the unfortunate owners of the restaurant where the subject of sudden death had eaten his last meal.

Neglecting the mechanical factor. It is said that there are still not a few doctors who think they can practise medicine with a thermometer, a stethoscope, a fountain pen, and a prescription pad. "If such there be, go mark him well" as a man who is neglecting great opportunities. The reason why an osteopath or a chiropractor occasionally succeeds in the treatment of a case where a regular practitioner has failed, is because the manipulator concentrates all his attention upon the mechanical relations which the more scientific physician overlooks or ignores. Hippocrates, says Allbutt, "had no more scruple in using his hands in the service of his brains than had Phidias or Archimedes." In this time and country Goldthwaite and his Boston confrères deserve great credit for presenting the mechanical aspects of the disorders of the human body in a rational and practical manner.

Consider the feet, how often they are treated for gout or rheumatism, with colchicum or salicylates, when the chief or only trouble is a static defect (weak foot, flat foot, short tendon, etc.) or else an arthritis originating in the gums, tonsils, or male urethra. True rheumatism of the feet is indeed almost unknown, except as a part of an acute febrile polyarticular infection. Gout, on the other hand, is probably of much more frequent occurrence in the United States than has generally been supposed. It is distinguished diagnostically by the usually nocturnal onset at the dorsum of the foot or base of the great toe, by the shining angry appearance with little or no fever and no suppuration, by highly uratic urine, and by its refractoriness to the salts of salicylic acid.

Again, if we keep a record of backaches, we shall find that much the most common cause is sacroiliac subluxation, or something akin to it, whereas kidney disease is a comparatively rare factor in pain in the dorsal region. I bring to mind the case of an old lady who had been treated with antirrheumatics more than a score of years, and who was at once relieved by strips of plaster about the pelvis, and a little later by the use of a well fitting leather belt.

In the study of gastrointestinal disorders, interference with the function of motility is most important, strictures, bands, and adhesions causing obstructive delay can now be inspected very satisfactorily by means of the fluoroscope and röntgenograms in conjunction with bismuth or barium meals and enemas. What is of the greatest practical utility, is that the x ray is often of unique service in determining whether or not a given abdominal condition requires surgical intervention. To Goldthwaite again the profession is indebted for a thoroughly scientific presentation of the relation of abdominal ptoses to abnormal postures and attitudes.

In every part of the body the mechanical factor may stand forth in clear perspective to the trained observer. For example, the commonest cause of night cough in children is irritation of the throat by mucus running down from the nose, and the logical treatment of such a cough (aside from surgical measures) is to keep the child's head high and soothe its nose and throat by the instillation of some bland oil.

Slighting the reflexes. Eating ice cream sometimes excites pain in the eye, owing to a reflex irritation from one of the maxillary branches of the trifacial nerve to the ophthalmic branch of the same nerve. So a decayed tooth may cause pain in the eye or ear; wax in the ear, pain at the tip of the shoulder; and hip joint disease, pain in the knee. I have at present under vaccine treatment a case of chronic antrum disease, in which, during exacerbations, the patient complains of pain and tenderness, not only in the affected malar region, but also in the lateral occipital region and over the spine of the scapula. Most of us have met with patients in whom irritation of the external auditory canal (as by wax in the ear or by local examination or treatment) has excited a dry cough. The explanation is that the auricular branch (Arnold's nerve) of the vagus lies in a groove adjoining the external auditory canal.

The pain and other symptoms of angina pectoris are ascribed by Mackenzie to a localized irritable spinal focus involving the lower cervical and upper dorsal nerves and their distribution on the side of the chest and neck, in the axilla, and down the inner side of the left arm to the little finger. Even the viselike sensation of severe angina he attributes to a visceromotor reflex affecting the muscles of the left side of the chest. I have known several cases of angina pectoris in which the pain was chiefly or wholly in the left arm, and a few of these patients had been treated erroneously for rheumatism. I recall also a case of pneumonia of the right lower lobe, with marked diaphragmatic pleurisy, involving the phrenic nerve, which was responsible apparently for pain in the right side of the neck as the chief subjective symptom.

We are all familiar with the referred pain in the back near the right shoulder blade in connection with gallstone disease, but Mackenzie calls attention to a much rarer reference, namely, to "the top of the right shoulder, striking down the outside of the arm." He has known such patients to be treated for years for "neuritis," in whom the passage of a gallstone has been followed immediately by relief. Gastric derangements, particularly flatulence and gastrectasis, may cause a similar referred pain at the tip of the left shoulder. In a woman treated recently for gastric ulcer of the posterior wall (verified by x ray plates), local hyperalgesia at the left side of the eleventh and twelfth dorsal vertebræ was much in evidence.

I have been among that considerable company who have mistaken a basal pneumonia of the right side (affecting the twelfth dorsal and first and second lumbar nerves, and thus giving rise to pain and rigidity in the right iliac fossa) for acute appendicitis. My patient was, happily, not operated on. Careful examination of the chest should prevent mistaking disease here for inflammation of the appendix, and a microscopic examination of the urine ought to aid in discriminating between stone in the renal pelvis or ureter and those rare cases of appendicitis with frequent urination.

Of all origins of referred and reflex sensory

symptoms, probably the prostate gland is the most prolific source of diagnostic error. It causes not only local soreness in the rectum and perineal region, but often a broad band of backache across the lower sacrum, a numb pain in both thighs, sometimes extending even to the heels, and a dull pain in the abdomen reaching to the umbilicus or higher. It seems to me that the greater number of attacks of so called sciatica arise either from sacroiliac strain or else from an enlarged and tender prostate—a condition determined or excluded in a moment by the introduction into the rectum of the rubber covered finger. There is a sort of pseudoparaparesis, accompanied by feelings of gloom and melancholy, readily relieved by thorough milking of the seminal vesicles and prostate with the middle finger. As a general rule in an obscure affection in a middle aged or elderly man, we should think of the prostate gland as a possible offender, and duly examine the parts per rectum and with a catheter (for residual urine).

Ignoring the psychic factor. Consciously or unconsciously, in the treatment of sick people we are constantly employing suggestion; but in diagnosing their complaints we are prone to overlook our patients' hidden griefs and worries—the pangs of unrequited love, the cares and trials of later life, and the great disillusionments which come to us all. Moreover, there is nothing too absurd, too senselessly superstitious for the human mind to give credence and act upon, from the blessed water used for bathing a sore knee to the gibberish gammon of the mercenary vampires of Christian science. The sexual instinct may be rampant or submerged, the traits reminiscent of lower animals (dog and hog in man, cat and peacock in woman) may obtrude obnoxiously, but I cannot think so meanly of the species to which I happen to belong as to believe in the Freudian scheme of cathartic psychanalysis.

A morbid desire for sympathy is the most prominent characteristic of the hysterical girl or woman. It is this longing to be petted and caressed which makes her an inveterate liar, telling of terrible pains (an inordinate capacity for morphine) with a smiling, mobile, and vacuous countenance, and simulating all the ills to which our flesh is heir. Other signs and symptoms which have seemed to me important in the diagnosis of hysteria are the curious twitching of the eyelids, ptosis, contraction of the visual fields; anesthesia of uvula and pharynx; aphonia coming on suddenly under excitement, and relieved by suggestion with or without material applications (such as freezing with ethyl chloride); tonic spasms with much ado accompanying, and promptly relieved by a hypodermic injection of apomorphine; astasia abasia or sudden hemiplegia (the face escaping), in connection with a dragging or shuffling gait; flatulence, transient polyuria, and globus hystericus; mammary, ovarian, and spinal hyperalgesia; analgesia of the glove and stocking type; and semistupor, with eyeballs fixed—quivering resistance of tremulous eyelids to opening—easily roused by firm pressure upon the supraorbital nerve in its notch above the eye. Most mysterious of all the symptoms of hysteria is the hyperpyrexia occasionally noted. Dr. L. T. Durbin, some time ago, reported before the Denver Medical Club a case of this kind in which the patient's temperature stood at 110° F. with no other manifestation of disease.

Diagnosis by proxy. "Letting George do it" all is a bad policy, even in medical or surgical diagnosis. No matter how wise and able are our confrères, we should always take their opinions *sub judice;* that is, with a grain or two of salt. On the other hand, the keen eyed specialist will frequently discover invaluable evidence not accessible to the average general practitioner. For example, in several instances I have known the oculist to make a definite diagnosis of chronic Bright's disease before the appearance of albumin and casts in the urine. What is most needed in the diagnostician is that fine judicial balance which weighs all the evidence in the case, from whatsoever source obtained, and calmly and without haste, seeing the whole matter in clear perspective, arrives at a conclusion in which every part of the symptom complex, past, present, or future, fits in its place like a brick in a house.

Diagnosis by predilection. How true it is that we see the things we look for, and fail to see those for whic! we do not search. Hence the neurologist may diagnose a case of pernicious anemia as myelitis, an aurist may treat the ear when the teeth are at fault, and a surgeon may operate at the site of a referred pain. Despite this natural and pardonable tendency to magnify one's own specialty, my observation has been that the great majority of specialists and surgeons are fully as honorable in the matter of operation or nonoperation as is the general practitioner in making or not making unnecessary calls. All of us need to be on the alert to avoid conclusions based upon our preferences rather than upon the premises. For myself, I recall diagnosing a case of varioloid in the early stage as a pneumococcic infection, having found a large number of pneumococci in a swabbing from the throat. On the other hand, I have had the good fortune in a number of cases of bronchitic asthma to determine the bacterial cause and, by means of autogenous vaccines, bring about considerable relief or even a clinical cure. One of these patients, referred by Dr. Joseph H. Allen, had found it necessary to inject adrenaline once or twice each night for six months, because of asthmatic attacks, from which she has now been practically free for nearly two years.

The pathognomonic delusion. No more frequent error is made, perhaps, than to base a diagnosis upon a single sign or symptom. For example, if a patient shows loss of knee jerks he is liable at once to be set down as a syphilitic suffering from locomotor ataxia. Yet there are at least thirty other conditions in which knee jerks are absent, and of these hysteria and multiple neuritis are probably most important.

Far be it from me to detract from the prestige of the laboratory worker, but in truth and in fact there is no part of applied medical science in which interpretation of the findings is of greater moment. To illustrate historically: My copy of William Beaumont's *Experiments and Observations on the Gastric Juice and the Physiology of Digestion*, edition 1834, gives correctly hydrochloric or muriatic acid as the normal acid of the gastric juice, the author's conclusion in this respect being fortified by tests made by Professor Dunglison and Professor Em-

mett, of the University of Virginia, and Professor Silliman, of Yale College. Dr. J. C. Dalton's *Treatise on Physiology and Hygiene*, edition 1876, which I studied the following year, gives lactic acid ("the same acid which is produced from sugar in the souring of milk") as the normal acid of gastric juice, in the proportion of 4.78 parts per 1,000. Next comes Ewald, edition 1892, who emphasizes the importance of the absence of hydrochloric acid and the presence of lactic acid as signs of gastric cancer; and a few years later, he recommends a breakfast of oatmeal (instead of bread and water) as being free from preformed lactic acid. The Boas-Oppler bacilli, when first discovered, were thought to be quite certain evidence of gastric cancer; but now we know that they simply depend upon an organic acid environment, that the absence of free mineral acid is a more constant token of pernicious anemia than it is of gastric cancer, and that the physiognomy of this disease is made up of a number of features, all of which must be brought together in order to recognize the disease. In connection herewith, I wish to emphasize the practical utility of a study of the cytology of the stomach washings, as recently practised by Caussade. It seems that cancer cells from the stomach, when properly obtained and stained in the wet state, are not at all difficult to determine.

When a housewife invents a new kind of pie, she becomes in a measure a mother to that pie, and forever after she will cherish it as the most delicious pie that ever was or will be. In much the same way the scientific investigator, having discovered a new test, can see nothing but good in it. Abderhalden's hypothesis of the protective ferments makes interesting reading, but the actual tests based upon his theories have but little practical value (the test for pregnancy, it is said, reacting positively with one third of all the men upon whom it has been tried), and, in short, Herr Professor Abderhalden is about the only laboratory man who still clings to these tests with unfaltering devotion.

Another imported test which is much overrated is that of Wassermann for syphilis. A fair statement of the present status of this test, based largely upon a report of 325 specimens of blood collected from 292 persons and sent to seven competent serologists (Uhle and MacKinney, *Journal A. M. A.*, lxv, 863, 1915), is given in an editorial article in the *Medical Record* for September 25, 1915, from which I take the liberty of quoting a few sentences: "From the normal and nonsyphilitic cases the positive results varied from 2.6 to 18.1 per cent. There were conflicting reports, but, what is worse, 'conflicting reports from the same serologist on specimens from the same individual withdrawn at the same time under identical conditions.' All of the laboratories agreed in twenty-one per cent. of the specimens, they disagreed materially in nineteen per cent., and varied in from one to four of the ten results (some serologists used more than one antigen) in sixty per cent. In other words, if a specimen of blood from the same individual be submitted to ten tests by different serologists, there is one chance in five that the tests will agree." What then can be said of the value of the Wassermann reaction as a diagnostic procedure? A single negative result certainly does not exclude syphilis, and even a series of them may be overruled in the presence of sufficient clinical evidence. We may, therefore, conclude that a negative result has little or no value except as it may confirm the clinical diagnosis. A positive test is a frequent symptom of syphilis; and therein lies its chief danger, for the most serious mistake that can be made is to pronounce a man syphilitic and thereby condemn him to a lengthy treatment and lifelong suspicion without adequate reason therefor. But the Wassermann is not pathognomonic of syphilis, since it occurs in other conditions (malaria, lead poisoning, pulmonary tuberculosis, diabetic lipemia, and acidosis), and it cannot be too strongly emphasized that a diagnosis of syphilis must not be made upon the Wassermann reaction alone." This reaction, it seems, depends in a measure upon the cholesterin content of the blood, which accounts for the fact, perhaps, that the ingestion of alcohol renders an otherwise positive Wassermann negative. For the same reason, probably, fatty foods tend to yield a pseudopositive reaction, and at the Mayo clinic (where, however, I understand, the Noguchi modification is employed), it is customary to starve patients until midafternoon before withdrawing blood for the test for lues.

Names without sense. The correct method of naming a disease is by combining etiology and regional pathology, as when we say streptococcal tonsillitis or tuberculous peritonitis. Many misnomers are still to be found in medical literature, and some of these are encountered nearly every day. Malaria has nothing to do with bad air, nor gout with a dropping, nor diabetes with a siphon, nor gonorrhea with a flow of semen, as the names would indicate. As for "rheumatism," the term is so much abused that we feel almost ashamed to make a diagnosis under this name. Dermatological nomenclature is particularly rich in names that sound well, but mean almost nothing; e. g., psoriasis (from the Greek word for itch, with which psoriasis was formerly confounded), eczema (a boiling out, or heat eruption), lupus (Latin for wolf), acne (the acme of life), pityriasis (bran), and erythema papulosum (a pimply redness).

The name neurasthenia (literally, nerve weakness) means little more than the corresponding archaic forms, general debility and nervous prostration, but it continues to roll its pentasyllabic length with unctuous euphony from the tongues of most medical men. The term simply implies, what the patient knows already, that his nerves are tired, and is really an obstacle in the way of more exact knowledge. The category in which a great many "neurasthenic" patients fit is the condition of vasomotor depression, or blood ptosis, admirably described by Crampton in the New York Medical Journal for November 8, 1913. Every day I make use of the table printed in his paper, and have found the patient's subjective state to correspond almost invariably with the changes in the vasomotor tone. These low vasotone cases complain chiefly of weakness, faintness, and dizziness on rising or walking, coldness and paresthesia of the extremities (the "x" disease of Mackenzie), and an all round deficiency in

that vigor and vim which made Sunny Jim so famous in his day. Of course, we must make sure there is no underlying anemia, syphilis, latent tuberculosis, diabetes, or other serious organic disease. Uncomplicated cases of lowered vasotone respond quickly and satisfactorily to large doses of strychnine, the free use of caffeinized drinks, and the cool spinal morning shower bath. For the frequently accompanying cardiac dilatation of the greater altitudes, tincture of strophanthus is usually efficacious.

Sheer ignorance. There is so much to learn and to forget in the practice of medicine, that it is no wonder the human mind fails at times to grasp the significance of individual signs and symptoms, or even mistakes the normal state for something abnormal. For example, in infants the liver, when the child is upright, reaches one half inch below the ribs, and the heart extends to the left nipple or beyond—and so the erroneous diagnosis of enlarged heart or congested liver is sometimes made. Young mothers, and occasionally young doctors, have been known to mistake the Epstein pearls, the whitish areas over the hamular processes of the palate bone, for a form of stomatitis. The minute miliary transparent bodies visible upon the soft palate of an infant's mouth are, according to Koplik, quite normal.

Mistakes of this kind remind one of the Christian science lady who had a cat, and she (the cat) had a litter of kittens, and "the poor little kittens were all born blind, but I prayed and I read *Science and Health*, and after ten days every little kitten got its eyesight just as good as anybody's—Glory be to Mother Mary Baker Glover Patterson Eddy!"

A field in medicine which has been barely explored as yet by such pioneers as Kocher, Sajous, and Cushing, is that of the ductless glands and animal extract therapy. Slight degrees of excess or insufficiency are especially liable to escape detection in the present state of general ignorance of this province, although such changes may easily account for otherwise obscure symptoms. I believe that when a thorough knowledge of the functions and interactions of these glands becomes an essential part of medical science, the physician will be able to play the harmonies of health upon the keys of life as never before. I further believe that quite possibly the control of the cell anarchy called cancer lies in the study of these glands, an hypothesis to be verified or nullified only by experimentation on the diseased human subject.

In conclusion, what words are more true and expressive than those of the master when he wrote, "Art is long, life is short, experience fallacious, and judgment difficult"?

METROPOLITAN BUILDING.

Treatment of Aortitis syphilitica.—J. W. Held (*Southern California Practitioner*, September, 1916) recommends salvarsan intravenously in doses of 0.1 gram every fourth day for three or four doses. The patient is to stay in bed. Following this sixteen doses of mercury salicylate of one quarter grain each are given intramuscularly twice weekly. Potassium iodide 0.5 gram three times a day is of great service. The kidneys must be carefully watched, as uremia frequently terminates the disease.

AN ACCESSORY OVARY.

BY ALLEN J. SMITH, M. D.,
Philadelphia,
AND ALFRED C. WOOD, M. D.,
Philadelphia,
(From the McManus Laboratory of Pathology, University of Pennsylvania.)

The occurrence of supernumerary ovaries is of course a well established fact, although there is reason to suspect with Sutton (1) and others that many of the reported cases are without sufficient verification, any small protruding or pedunculated solid bodies in the vicinity of the ovaries being apparently accepted without full histological examination as being of ovarian character. There exist in literature, however, numerous indubitable cases; to the list of which, without detailed comment, the writers desire to add the following.[1]

On May 1, 1916, Doctor Wood removed the uterus and right appendages (leaving behind for the usual definite physiological reasons the left appendages) from Mrs. L., white, widow, aged fifty-two years. About a year previously he amputated the left breast because of a carcinoma of five years' duration, and since then had had the patient under general observation. No recurrence or metastasis of the cancer had appeared in the interim; but owing to indefinite pelvic symptoms a vaginal examination had been made which led to the recognition of an apparently diffuse uterine enlargement believed to be due to fibromatous involvement, hysterectomy being undertaken for this reason. The woman had

FIG.—*a*, Accessory branch of ovarian ligament; *b*, ovarian ligament; *c*, tube; *d*, ovary; *e*, round ligament; *f*, open lutein cyst of accessory ovary; *g*, cervical stump.

[1]For discussion and bibliography bearing upon this anomaly reference may be made to such a publication as Mauclaire and Eisenberg-Paperin, Les ovaires surnuméraires, *Arch. gén. de chir.*, Paris, v. 7, 1911, pp. 755-789.

never ceased menstruating. After the operation recovery followed without unfavorable complications. The specimens as noted in the laboratory records (No. 5181) presented the following gross features: The uterus was enlarged and of subglobular shape, with its external surface smooth and glistening, save on the posterior aspect, where there was slight fibrous roughening (but no definite adhesive bands). The full external measurements of the organ were: Length, fourteen cm.; width, 12.5 cm.; anteroposterior diameter, ten cm. On section the enlargement was found to depend upon a single large nodule, growing in the posterior wall of the organ, expanding it, and causing it to bulge especially in the dorsal direction. This growth, well defined and encapsulated, was softer and pinker than the common uterine fibroids; and proved on histological examination to be a practically pure leiomyoma. The right tube was eight cm. in length; in its fullest diameter one cm.; somewhat coiled, with the coils fixed by old fibrous bands, but without evidence of adhesion to the surrounding parts. Its fimbriæ were well formed and free; the ostium was open. The right ovary was small, shrunken, firm, with nodulated surface, and on section presented the gross appearance of a sclerotic ovary; which features were confirmed by microscopic examination. A small parovarian cyst existed in the usual position. In the right parametrium, nearer the uterus than the ovary and at a slightly lower level than that of the ovary, there projected dorsally from the broad ligament a ruptured cyst, the contents of which had been lost. It protruded dorsally over the two cm. beyond the surface of the broad ligament upon a circumscribed base; but was apparently covered by the peritoneal lining of the broad ligament. It measured 2.5 by 1.7 by 1.5 cm.; had a smooth lining on which at places a soft fibrinlike material was evident. Its walls were thin, for the most part about one mm. in thickness, the tissue of the wall was soft and fleshy, finely dotted with yellowish marking. No strands of similar tissue extended from this to the ovary proper; nor were there fibrous bands of special formation between them. The ovarian ligament, however, in its course to the ovary proper gave off a grossly visible branch to the base of the cyst. Histologically, the wall of the cyst presented the appearance of a slightly sclerosed ovarian stroma, with small corpora fibrosa evident here and there, but without definite follicles apparent in any of the sections examined. The lining of the cyst was made up of organizing lutein tissue, with a reticulated fibrinous and hemorrhagic inner surface. Such features indicate this structure to be a lutein cyst in aberrant ovarian tissue, apparently imbedded in the parametrium and without recognized connection with the ovary proper.

These aberrant ovarian masses are usually classified (2) in three groups: *a*, accessory ovaries (ovarium succenturiatum, of Beigel), *b*, bipartite and pluripartite ovaries, in which traces of ovarian tissue or of fibrous strands connect the anomalous with the proper ovarian structure, and, *c*, true supplementary ovaries or entirely separate organs, which may have their own ovarian ligaments and even their own supplementary tubes. The specimen here recorded is to be classed in the first of these groups.

Aside from the mere anatomical interest in such occurrences, the importance of the abnormality lies in the probability of anomalous ovaries causing persistence of menstruation after supposedly complete oophorectomy, and in the fact that they are not infrequently found to be the seat of dermoids and other types of cyst and tumor formation.

THE THERAPEUTICS OF CERIUM.*

By Reynold Webb Wilcox, M. D., D. C. L.,
New York,
President, American College of Physicians.

Cerium was discovered by Berzelius and Hisinger and by Klaproth, independently, in 1803, and was named after the planet Ceres, discovered in 1801. It is associated in its natural state with lanthanum, discovered by Mosander in 1839, and with didymium, discovered by the same chemist, in 1841. Later it was found by Welsbach that didymium consisted of neodymium and praseodymium, and their oxides were studied by von Scheele. Cerium has always attracted much attention because it is the only "metal of the earths" used in medicine under its name. Chemically, cerium resembles aluminum in its behavior, while it acts medicinally like bismuth and silver. Cerium oxalate was produced by Mayer, in 1860, and is insoluble in the simple solvents; the carbonate and bromide are insoluble, while the nitrate is freely soluble in water. The oxalate, official in the Pharmacopœia of 1870, was likely to contain, as impurities, earthy phosphates, carbonates, aluminum salts, heavy metals, metallic oxides, foreign oxalates, arsenic, and zinc. The chemical formula is $Ce_2(C_2O_4)_2+10H_2O$. The proportion of true cerium oxalate in commercial specimens varies from 44.43 to 46.59 per cent. The other rare earths are didymium, calculated as oxalate, 26.08 to 39.01 per cent., which naturally includes both neodymium and praseodymium, and lanthanum. Boelen, however, reports that the examination of a large quantity of medicinal cerium oxalate gave the following results: Cerium oxide, 21.35; lanthanum oxide, 24.16; neodymium, 11.96, and praseodymium, 24.20 per cent., respectively. Inasmuch as cerium oxalate is a byproduct in the separation of thorium from monasite sand, and inasmuch as the separation of pure cerium from this complex mixture is a difficult and expensive process, we must content ourselves with this mixture of rare earths, which contains about forty per cent. of pure cerium. Power and Shelden, in 1877, stated the matter fairly:

> In view of the complex character of commercial cerium oxalate and the tendency of modern medicine to employ pure substances of a definite composition, the question naturally suggests itself, whether the pure salt would not be more suitable for medicinal use? It is important to consider in this connection that the original observations which led to the introduction of cerium oxalate as a therapeutic agent were based upon the use of the commercial salt, and even at the present time pure cerium oxalate pos-

*Read before the American Therapeutic Society, at Detroit, June 9, 1916.

sesses a market value which is about fifty times that of the pharmacopœial preparation. It is possible that all of these salts possess similar therapeutic properties.

Coblentz states that we cannot control the composition of commercial cerium oxalate by tests either qualitative or quantitative, and we dare not set a limit on the pure cerium oxalate present, for no one seems to know to which of its several constituents it owes its medicinal properties.

Laboratory investigation as to the action of cerium and its associated elements is not very illuminating. Cushny found that when cerium oxalate was injected into the circulation it produced gastrointestinal irritation, vomiting, diarrhea, hyperemia, and congestion of the mucous membranes, and congestion and inflammation of the kidneys. Branton and Cash, investigating the action of didymium upon the nerves and muscles of frogs, reported that it did not increase the reflex action of the cord nor diminish it until the last; it appears to paralyze the higher centres. It diminishes the coordinating power, rendering the movements ataxic, although neither nerve nor muscle is paralyzed. Didymium diminishes muscle contractility, but the duration is unaffected or slightly diminished. It is poisonous in the proportion of 0.0042 of the body weight. On a frog weighing eighteen grams, an injection of 0.075 gram of didymium chloride caused symptoms as follows: The animal became difficult to arouse to movement, while reflex response still remained good; it was plastic and lay in an unnatural position. Later, reflex action became more feeble and slow; circulation was at first good, but gradually ceased. After death the heart was at a standstill in moderate diastole, but went again on stimulation. On local application, one in 100 solution does not materially alter the length of curve, simply reducing altitude somewhat without materially altering its form. Contraction in resting muscle is increased. Mills found that after twenty grains of commercial cerium oxalate had been administered in twenty-four hours, no cerium was found in the urine, nor was didymium detected even by spectrum analysis.

That cerium oxalate does not produce untoward effects, even when administered in large amounts, is evident from the instance reported by Roberts Bartholow, when four grains were given every two hours for vomiting until 600 grains were administered. He remarks that even larger doses are often necessary.

The pharmacopœial cerium oxalate has not been thoroughly investigated from the physiological, nor have satisfactory tests been devised from the pharmaceutical standpoint, yet it has been considered a valuable remedy, not infrequently prescribed by expert therapeutists, who believe that it is useful in a limited array of maladies.

Cerium became known to the medical profession in 1854, principally through Simpson, who recommended it for irritative dyspepsia, especially of sympathetic origin or dependent upon pregnancy as "the simplest and surest remedy," in pill form, in one or two grain doses. Mills confirmed this in 1876, with nausea as an added indication, and for the vomiting in phthisis and typhoid fever. Campardon recommends the remedy for nervous vomiting and Blondeau for the vomiting of pregnancy; the latter adds that sleep is benefited. Good results have been asserted in cough and vomiting from irritation of the terminal filaments of the pneumogastric in the stomach mucous membrane. Deranged innervation of the stomach, as in seasickness and reflex vomiting in uterine disorders and displacements, are cited, and, finally, in 1879, Busey found cerium oxalate valuable for the nausea and headache which follow the administration of opium.

Of disturbances in the alimentary tract, chronic vomiting, gastric acidity, gastrodynia, pyrosis, gastric ulcer and cancer, and chronic diarrhea are found in the literature as indications for its use, and Clark recommended it, in 1880, for cholera infantum in four tenths of a grain doses every hour for children under one year of age.

Finding that vomiting associated with cough was relieved, Clark, in 1878, prescribed cerium oxalate for the morning cough of chronic pulmonary diseases, and stated that the accompanying dyspnea on exertion was also alleviated, five grain doses being exhibited before rising, which sometimes relieved for twenty-four hours. The only untoward symptom was dryness of the mouth. It was also stated to be of benefit for the cough in chronic bronchitis, and had been recommended for whooping cough.

From so called nervous vomiting it was but a short step to the advocacy of the remedy in nervous diseases. Good results were obtained by Image, in 1878, with ten grain doses every four hours in hysteria from anxiety, grief, or overwork. Simpson believed that the remedy was a nerve tonic of value in chorea, two to ten grains several times daily, while Bechterew advised its use in epilepsy, and even in the crises of locomotor ataxia.

With our present knowledge of the absence of absorption of the mixture of rare earths known in the Pharmacopœia as cerium oxalate, we can safely eliminate from our nosological list all diseases in which the effects of the remedy are remote. With the passing of the reflex and a more correct interpretation of symptoms and signs as indicating pathological conditions, we can still further limit the indications for its use. Basing our therapeutics upon clinical experience, the use of cerium oxalate will be limited to conditions from which we expect to get results from local application. Certain nauseas and vomitings will remain, and even here we shall entertain a watchful skepticism that it may not be altogether the one grain dose of the Pharmacopœia, or the minute dose of some alleged antiemetic which is followed by a disappearance of the symptom, but possibly the withholding of other more active drugs, or even of food, which is responsible for the result.

Finally, we can safely assert that cerium oxalate resembles bismuth subnitrate in its therapeutic action, with the advantages that it does not give rise to an unpleasant odor to the breath, owing to the presence of tellurium, and that it is not usually contaminated with arsenic as is the latter.

The therapeutic uses of cerium oxalate are simi-

lar to those of bismuth, which are for local effect, and success requires that the doses should be of a magnitude commensurate with the results which we desire to obtain, namely, ten grains every four hours. Further than this, this dose should be frequently exceeded, as we now know can be done with safety; thirty grains have been administered with good results.

Bearing these facts in mind, the results of twelve years' experience in the use of this remedy, have been confirmed by skilled therapeutists in internal medicine, and have shown conclusively that cerium oxalate, when used in proper doses, and with due discretion, will produce typical and satisfactory results; its therapeutic value cannot be disputed.

TREATMENT OF BLADDER TUMORS.*

By J. T. Geraghty, M. D.,
Baltimore.

(From the James Buchanan Brady Urological Institute, The Johns Hopkins Hospital.)

The selection of the proper treatment for tumors of the bladder depends upon the determination of many factors, most important of which is the ascertaining of the nature of the tumor. Other factors, such as position, extent, and number of tumors, presence of metastases and complications will all play roles in determining the best method of attack. From a therapeutic standpoint, we have divided our tumors into papilloma, benign and malignant, papillary carcinoma, and in a separate class we place the adenocarcinoma, squamous and scirrhous carcinoma, because, as will be later shown, the handling of papillary carcinoma requires a technic very much more developed than is necessary for the handling of the other carcinomata.

From a therapeutic standpoint we have placed benign and malignant papillomata in the same group, although from a histopathological viewpoint malignant papillomata are just as much cancer as the papillary carcinomata, yet they must be differentiated because of their different response to therapeutic measures. In malignant papilloma there is present principally changes in the shape, staining properties, and nuclei of the epithelial cells without any marked evidence of cancerous infiltration. Experience, however, has shown that these changes are indicative of cancer, and that patients die of cancerous metastases when these changes in the papillæ are the only evidence of malignancy which exist. In a series of twenty-five papillomata examined histologically sixty-eight per cent. showed the changes characteristic of malignant papillomata. When, however, the malignant papilloma has advanced to the point where infiltration of the bladder wall occurs, we apply to it the term papillary carcinoma. This differentiation is arbitrary and is used simply as a working basis.

For a number of years we have systematically excised pieces of bladder tumors and studied them with care histologically, in an endeavor to see if there was not some histological picture which would clearly direct us in the selection of the most suitable form of treatment. It has been our experience that in the vast majority of cases we are not able from the histological picture alone to decide with accuracy whether the tumor will respond to fulguration or whether more radical procedures should be adopted. Repeatedly we have excised pieces of papillary carcinoma and found the histological picture no different from that seen in the average malignant papilloma, while the clinical examination indicated most extensive infiltration, which was subsequently corroborated by the course of the disease. As a differentiation between malignant papilloma and papillary carcinoma, we have found cystoscopy, combined with other clinical methods, a greater aid than the histological picture alone. Finding on cystoscopic examination the presence of necrotic papillæ on an otherwise benign looking papilloma, the presence of edema around the margin of the tumor or nodules in the mucous membrane in the neighborhood of the tumor, the presence of an intractable cystitis, and, when tumors are situated on the posterior bladder wall, feeling on rectal examination the slightest induration therein, are points in the differential diagnosis which have served us best. It must be admitted that none of these conditions may be present and the tumor may still have invaded the bladder wall. When in doubt concerning the nature of the tumor, our practice has been to adopt fulguration as a therapeutic test. After a few applications of the fulguration current, it can usually be determined whether the tumor is suitable for this form of treatment. When the surface of the tumor is vigorously fulgurated and the slough does not separate, or when it becomes covered with calcareous deposit, this is evidence of advanced malignant changes in the deeper portions of the tumor.

FULGURATION.

Fulguration has been employed in fifty-three cases; in twelve cases the tumors were inoperable carcinomata, and fulguration was employed as a palliative measure or to test out the efficiency of the treatment in that type of case. In none of these cases was any marked impression made upon the tumor, while the treatment was rather painful in the scirrhus type. Among forty-one cases with papillomata, in thirty-four per cent. of which the tumors were multiple, in three treatment ceased before the tumors had disappeared. In two cases, although the tumors were small and apparently papillomata, the response to fulguration soon indicated that they were really papillary carcinoma. In one of these a successful reaction was subsequently obtained; while in the other case, that of a very elderly man, a senile dysentery developed, and auricular fibrillation, of which he soon afterward died. In the remaining thirty-six cases the tumors in every instance entirely disappeared. There seems to be a marked difference in the promptness of response to fulguration between the benign and the malignant papillomata. The typical benign papillomata vanished with astonishing rapidity, large tumors disappearing with comparatively few treatments. On the other hand, malignant papillomata disappeared slowly, and frequently required many times the amount of treatment which would be necessary for the benign papillomata of the same size. In one in-

*Read before the New York Academy of Medicine, April 27, 1916.

stance it required almost nine months completely to remove a malignant papilloma which covered the whole left lateral wall and was composed probably of not one tumor but of multiple papillomata fused on the surface, giving the appearance of one broad, extensive tumor. In this case we were led to continue this form of treatment because of the definite and progressive decrease in the size of the tumor and the rapid separation of the burned areas after each treatment. Of twenty-five papillomata examined histologically, seventeen showed the changes characteristic of malignant papilloma, but all were removed by fulguration, the benign and malignant differing from each other only in that the response was slower in the malignant types. The incontestable proof that at least some of these tumors were malignant or cancerous is that two of them were subsequently fatal through cancerous metastases, although the bladder was free from tumor.

RECURRENCES.

Of the thirty-six patients in whom fulguration was successful in removing the original tumor or tumors, recurrences are known to have occurred in seven. In all of these, with one exception, recurrence was present in less than a year. In one patient, recurrences are observed every few months, although it has been over three years since the original tumor was destroyed. This tendency to recurrence seems as active today as it was during the first year. The recurring tumors, with one exception, have all responded to fulguration like the original tumor. The one exception is of extreme interest (Roeder). This patient had a papillary tumor, several cm. in diameter, just back of the ureteral orifice, which disappeared fairly rapidly under a combination of radium and fulguration. For several months after the disappearance of the tumor the mucous membrane of the tumor bearing area seemed entirely healthy. Shortly afterward, however, cystoscopic examination showed a peculiar reddening and some slight bulging of the mucous membrane without ulceration or definite tumor formation. This was at first thought to be a localized inflammatory area. The process, however, seemed to spread, and a piece removed with the cystoscopic rongeur showed the patient to have an infiltrating carcinoma of the bladder wall, with the mucous membrane on the surface practically intact. This is undoubtedly a case in which cancer cells from a malignant papilloma have metastasized into the deep bladder wall and there continued to grow after the tumor mass had been entirely removed. A malignant tumor of this type has been studied histologically by Buerger. Patients with multiple tumors seem more apt to have recurrences than those in whom only one tumor is present. While it is too early to draw definite conclusions regarding the percentage of cases that will remain permanently cured, the results to date seem to warrant belief that a not inconsiderable proportion will be free, because the tendency for recurrence grows progressively less after the first year.

EXCISION.

Until a few years ago, excision of bladder tumors with the knife, clamp, and cautery, or the actual cautery, was the method most frequently adopted. In our series of tumors there have been thirty-four in which excision was carried out by one of the foregoing methods. Of these thirty-four only four were known to be well and free from recurrences during a period of four years or over. It is difficult to explain why such dismal failure should have resulted from this form of treatment. In some of the earlier cases, before the true nature of the bladder tumors was clearly recognized, sufficient care to avoid implantation was probably not exercised. In later years, however, a more careful technic was employed in the handling of these cases, and measures were adopted to prevent implantation on the remainder of the bladder wall. It seems difficult to understand why a pedunculated papilloma should not be radically and thoroughly removed, by excision, or by the clamp and cautery, or by the actual cautery, and the failure to accomplish cures in many of these cases must be attributed to the difficulties in securing a technic sufficiently perfect to prevent trauma to the bladder wall and implantation of tumor cells. The smaller percentage of recurrences in the cases treated with fulguration, compared with the cases in which excision has been employed, seems to point strongly toward the supposition that the difficulties of obtaining a perfect technic for the removal of these tumors is an important cause of past failures.

Excision is a surgical procedure which today is seldom indicated; it should be used only in cases which ordinarily would be suitable for fulguration, but on account of some complication that treatment has become impossible or very difficult. The systematic opening of the bladder, with subsequent prolonged fulguration of tumors, is a procedure which cannot be recommended, and for the average case offers no advantage, but rather disadvantage over the intravesical procedure.

RESECTION.

The failure of excision to cure more than a very small percentage of bladder tumors, benign or malignant, led surgeons to adopt more radical measures, so that during recent years resection for all tumors, namely the complete removal of the tumor bearing area, together with all the coats of the bladder wall, has been the procedure advocated.

Experience has shown that when the growth has infiltrated the bladder wall, resection with as wide a margin of healthy mucous membrane as seems necessary, is the only method which offers hope of success. Resection is indicated when the tumor is of such a size that it can be completely removed, even though it necessitates the transplantation of one or the other ureter. It is generally conceded that resection should not be undertaken when the tumor has infiltrated close to the vesical orifice, and particularly when it has invaded the prostate. It is also questionable whether resection should be performed when the tumor is so extensive that transplantation of both ureters will be necessary. When the tumors are multiple, resection again is contraindicated unless the tumors occupy an area which will allow of their removal in one piece. Tumors occupying the anterior bladder wall are most favorable for resection. The transperitoneal method, except in occasional cases, is not to be recommended, as a suffi-

ciently perfect exposure can be secured without subjecting the patient to this unnecessary risk.

TECHNIC.

The position and size of the tumor should be determined as accurately as possible before operation, by means of cystoscopy. The bladder should be emptied of urine and filled with air, so that when the bladder is subsequently opened an infected fluid may not soil the incised tissues. Immediately on opening the bladder, which should be done in such a way as to avoid trauma to the tumor, the tumor should be thoroughly cauterized *in situ* before further manipulations are carried out. In order to avoid sponging, a glass tube connected with a suction pump should be placed in the base of the bladder, but not allowed to come in contact with the tumor. If sponging becomes necessary, sponges wet with alcohol should be used, and the sponge which comes in contact with the tumor bearing area should not be used on other portions of the bladder wall. The main emphasis should be laid on the thorough destruction of the tumor by the cautery before resection is attempted. This having been done, the bladder wall can be incised with the cautery or knife with less danger of implanting tumor cells. Resection has been the operation carried out in twenty-four of our patients, and nine of these were well two years or longer after the operation. Of these nine, five belonged to the malignant papilloma type and four were small circumscribed papillary carcinomata in which it was possible to remove a considerable margin of normal bladder wall. In none of the carcinomata extensively invading the bladder wall has a cure been obtained.

RADIUM.

During the past eighteen months, we have treated about fifteen tumors with radium alone or with radium in combination with fulguration. Our experience has not been sufficient to draw definite conclusions regarding the ultimate value of this method. It has been employed most frequently on malignant papillomata in combination with fulguration, and the effect of the radium has been most striking. In three cases in which fulguration had been employed over long periods of time, and which had resisted very stubbornly all efforts to entirely destroy them, radium seemed entirely to change their nature. In all three cases after receiving 500 to 600 mg. hours of radium applied directly against the tumor, the latter disappeared with astonishing rapidity on resuming fulguration. When possible, the radium is applied directly against the tumor by means of the Young radium cystoscope, using a tube with an opening on one side, so that the beta rays can be applied directly to the tumor while the rest of the bladder wall is screened. The combination of radium and fulguration in this type of case seems to promise much. So far, we have not succeeded in definitely eradicating the papillary or other infiltrating types of carcinoma.

CYSTECTOMY.

Cystectomy has been employed in only a few isolated instances in our series. The operation, while technically not difficult, leaves the patient in such a distressing and uncomfortable condition that we hesitate to adopt this most radical procedure. Furthermore, the percentage of cures following cystectomy has not been sufficiently large to make us very enthusiastic. Usually in cases which are so far advanced that this method of attack forms the only hope of removing the local condition, metastases are generally present. Metastases occur even when the tumor is small and apparently well localized in the bladder, and Claido reports four observations in which iliac and lumbar glands were extensively invaded, although the tumor had not seized upon the wall of the bladder. Such has also been our own observation. While there are no convincing statistics regarding the frequency of glandular metastasis when the tumor is well localized in the bladder, it is generally admitted, when the tumor is extensive and infiltrates deeply the bladder wall, that metastases are practically always present. That the tumor may in rare instances be very extensive and even deeply infiltrating without metastasis, has come under our personal observation.

Cystectomy in the past has not seemed a procedure which we felt justified in carrying out.

PALLIATIVE TREATMENT.

A distressingly large percentage of bladder tumor cases present themselves in the urological clinic for the first time with the disease so far advanced that nothing more than palliative measures can be employed. Of our series of 180 cases of bladder tumors, in sixty-nine the tumors were so extensive and so hopelessly inoperable that nothing more than palliative measures were adopted.

CONCLUSIONS.

The experience in our clinic in recent years indicates clearly that benign and malignant papillomata should be treated by fulguration; excision or resection should not be practised except where intravesical treatment is impossible or very difficult. Radium has been a great aid in the treatment, particularly of the malignant papillomata, and our best results have been obtained when the radium was placed directly against the tumor. When the tumor is a papillary carcinoma, resection should be practised by a technic which will reduce to a minimum the dangers of implantation or recurrence. Radium as yet has not given us results in this type of tumor sufficiently encouraging to warrant our employment of it in preference to resection in cases which are considered operable. Following resection, cystoscopy should be performed at an early date, and at frequent intervals, especially for the first year, and if recurrences are noted, they can occasionally be successfully treated by a combination of fulguration and radium. Unfortunately, as already stated, a large percentage of cases are first seen with the disease so extensive that nothing more than palliative measures can be adopted.

Spontaneous Diabetes in a Dog.—Krumbhaar (*Journal of Experimental Medicine*, October, 1916) reports a case in which the characteristic lesions of the pancreas were present.

TUMORS OF THE BLADDER.*

Their Pathology and Particular Reference to the Diagnosis of Papilloma and Carcinoma.

By Leo Buerger, M. D.,
New York.

Although much has been written about the difficulty of differentiating with certainty between carcinoma and papilloma of the bladder, very few, if any systematic and comprehensive pathological investigations have been made from both histological and clinical viewpoints, with correlation of the findings. It is generally believed that such differentiation is often impossible and that neither the cystoscope nor the pathologist can give definite opinions. From a study of 113 tumors of the bladder that have come under our observation at the pathological laboratory of Mount Sinai Hospital during the past ten years, and from a study of other vesical tumors, more than twenty-five in number, where the material, however, was not sufficient to be included in the series, we have come to the conclusion *that the pathological diagnosis of carcinoma is possible in most cases.*

The recognition of carcinoma of the bladder on a pathological basis must depend on the following: 1. Morphological characteristics varying from the benign type *do occur* when a tumor either possesses or has acquired the clinical traits of malignancy; 2, material can be obtained in which certain morphological criteria indicative of malignancy can be demonstrated; and, 3, the examiner possesses the power to recognize these criteria when they do occur.

In the course of this demonstration it will be shown definitely that morphological changes do occur in most instances; in fact, in all the cases of carcinoma of the papillary variety with but one exception was this the case.

As regards the obtainment of material, methods for carrying this out have been suggested in previous papers,[1] the use of the operating cystoscope having been recommended, together with the punch forceps, or the snare, in cases of papilloma.

It was only after a thorough pathological investigation of papillomata and carcinomata, that the conviction was forced upon us that certain peculiar abnormalities in the conformation of the cells regularly mean the presence of either primary carcinoma or carcinomatous change in papilloma. These abnormalities are cells manifesting irregularities in size and shape; nuclei rich in chromatin, staining deeply and of bizarre shape; cells with atypical mitoses; giant cells and multinucleated cells. All these, when occurring in papillomata of the bladder, indicate the presence or beginning of carcinomatous change. It will be granted that certain variations in the type cell belong to the benign growths, and that the proper estimation of such changes depends to a great extent upon personal interpretation. It is also true that in such matters as these no hard and fast rules can be laid down, and we can only in a general way indicate from personal observation what types of variations from the normal can be regarded as indicating malignancy. In the case of other organs, such as the thyroid, the liver, etc., atypical cells *per se* cannot be regarded as such evidences. In the bladder, however, our experience has led us to conclude that whenever such cells are present a thorough search will often disclose other evidences of malignancy. Another and most reliable evidence of carcinomatous change will be found in a disturbed relationship of the cells to each other in a loss of the typical palisade arrangement of the cells, in the presence of long fusiform or compressed types of cells, in the existence of evidences of infiltration of the stroma and penetration of the basal membrane, in the presence of cells in the capillaries, and, finally, in the occurrence of epithelial cells in the submucosa or muscular coats of the vesical wall.

These criteria have enabled us to recognize the presence of a malignant tumor in seventeen cases where the material would have led to an incorrect or doubtful diagnosis, if our present standards were rejected. If we accept these criteria we shall also be able to diagnosticate malignancy from a relatively small amount of material, and the report "insufficient for diagnosis," such as is often made by the pathologist, will be less frequently given.

The morphological criteria are present in parts of the tumor that are accessible to our diagnostic methods, occurring in papillomata that have undergone early malignant change, and certainly also in the primary carcinomata.

Perhaps the most instructive variety of papillary carcinoma is that in which we have reason to believe a papilloma is undergoing malignant change. The question whether this occurs or not, has been a mooted one for many years. Pathologists have expressed diametrically opposite views, although the present weight of opinion seems to favor the assumption that carcinomatous change does occur in papilloma.

Our own material has yielded us ample clinical and pathological corroboration of our view that a metamorphosis of papilloma into carcinoma does occur. Furthermore, we are of the belief that such a change takes place very frequently and could be demonstrated in at least thirteen out of our fifty-two cases of carcinoma; namely, twenty-five per cent. Some of the most instructive of our specimens are those obtained before the year 1910.[2] At that time almost all of the tumors of the bladder were at once subjected to suprapubic cystotomy and total excision, so that in these a thorough examination of the mode of origin of the carcinomatous change could be carefully investigated. From our specimens we were able to conclude, first, that carcinomatous change in a papilloma is possible and does occur frequently; second, that the change occurs in accessible portions of the tumor, that is, not in the "depth," as has been generally assumed to be the case, but anywhere in the surface or in the deeper

*Abstract of a paper read before the Section in Genitourinary Surgery, Academy of Medicine, May, 1916.

Journ. Surg.*, Feb., 1915.

[2] Since 1910 many cases have been treated with the high frequency method, so that minute pieces derived from bladder washings of specimens excised through the cystoscope represented the only material sent to the laboratory in many instances.

parts of the villi; third, that in the early stages the villi alone may be involved; fourth, that villous changes may be accompanied by infiltration, by invasion of the deeper parts, or by metastases in the capillaries; fifth, that all stages in the transformation of a papilloma into carcinoma can be followed in the various specimens up to the point of complete transformation or even to the stage where an infiltrating carcinoma involves all the coats of the bladder wall.

We have been able to group the various changed papillomata into six groups, depending upon whether first, epithelial changes alone were present; second, where changes in the cells together with infiltration of the stroma coexisted; third, where extensive cellular changes with invasion of the capillaries of the stroma could be found; fourth, where there were surface changes in cells, cellular changes in the stroma, and nests of cells in the pedicle; fifth, where extensive surface epithelial changes, slight foci of invasion into the pedicle could be found; and, sixth, where there were surface changes with distinct carcinomatous change in the periphery of the growth, the pedicle and the stroma being intact.

The various types of papilloma and carcinoma may be grouped as follows:

1. Papilloma.
2. Infiltrating papilloma.
3. Papillomata with early changes into carcinoma.
4. Primary papillary carcinoma:
   a. Papillary polypoid type—Carcinoma, Type I.
   b. Secondarily infiltrating carcinoma—Carcinoma, Type II.
5. Primary squamous celled carcinoma:
   a. Infiltrating derived from papilloma.
   b. Squamous type derived from papillary tumors.
   c. Those derived from the prostate.
   d. Metastases from source outside of the bladder.

1. *Papilloma.* The characteristics of papilloma have been sufficiently enumerated. It is necessary to obtain a large part of the growth for histological examination. This can almost always be accomplished if the snare is used. In order to be sure that the peripheral portions of the growth have not become carcinomatous, we must excise the mucous membrane of the periphery with the punch forceps. In the case of the sessile type of growth, the snare is usually not applicable, and we must resort to many bites of the cystoscopic punch forceps or the Young rongeur.

2. *Infiltrating papilloma.* Here we are dealing with the most difficult problem in the diagnosis of papillary tumors of the bladder. The presence of larger areas of muscle between the islands of epithelium points to the existence of infiltration. The diagnosis of malignancy can be definitely made upon this point.

3. *Papillary tumors with beginning carcinomatous change.* In this group there are six different types according to our fifteen specimens. Reviewing these, a striking fact is noted: that the first and the most extensive carcinomatous change occurs near the surface, and not in the *depth*, as has been previously supposed, the tufts always showing evidences of malignancy. The villi are markedly affected in all. If in Type II we disregard the changes in the villi, we should have to find the places where the stroma is infiltrated, and even this has occurred distal to the pedicle. If in Type III we should not recognize the extensive carcinomatous changes in the villi, we should have difficulty in looking for capillaries or small islands in the depth. If we disregard the cell changes in Type IV we should also have to seek in the depth for corroborative evidences. In Type V the same is true, except that the invasion is not so far from the surface, and in Type VI, if we disregard the surface changes we should have to find that area of the periphery which has become typically altered.

In short, the diagnosis of papillary growths with early carcinomatous change depends not so much upon the acquisition of a large amount of material as upon our ability to detect and give the proper dignity to the early morphological alterations characteristic of carcinoma, for these changes do occur, as has been pointed out, in the tufts of all six varieties. In only two out of the fourteen growths were there evidences of infiltration or tumor growths in the bladder musculature or deep down in the pedicle. On the other hand, more common was the association of the atypical cells in the villi, together with the infiltration of the stroma of the villi distal to the pedicle. This was presented in six cases; that is, cases in which the infiltration of the stroma could have been demonstrated in specimens obtained by punch forceps or snare, because changes were found on the tumor side of the pedicle. In three cases, only changes in the superficial portions of the tumor were found; that is, in portions of the tumor distal to the pedicle.

We see that in practically all of these early papillary growths, the diagnosis can be made if the criteria are accepted, and if a reasonable amount of material is obtained for miscroscopic examination.

4. *Primary carcinoma.* In these we should find no difficulty in making a diagnosis, since any portion of the growth is absolutely characteristic. They present practically no difficulties to the experienced microscopist.

5. *Secondary carcinoma.* First, those arising from papillomata and infiltrating the wall of the bladder are easily recognizable on sufficient material; second, the squamous type, which has been changed from a papillary carcinoma, can be diagnosticated from a small number of cells; third, the secondary carcinomata from the prostate have small cells as a rule, or may be tubular carcinoma or adenocarcinoma, and the metastases may be of various types, depending upon their source. None of these should give the pathologist any difficulty in diagnosis.

There remains for consideration the squamous type of carcinoma, which was represented in five cases. Cystoscopically these present a typical picture. These tumors are comparable to epitheliomata of the lip, and the structure under the microscope is similar.

CONCLUSIONS.

From a study of 113 tumors of the bladder, among which there were fifty-five papillomata, forty-five papillary carcinomata, five squamous carcinomata, two metastatic carcinomata, and six sarcomata, we concluded that a differential diagnosis between papillomata and carcinomata can be made in almost all cases on a pathological basis.

Certain morphological criteria were accepted as indicating the existence or the acquisition of malignant traits in any given tumor. These criteria were found to be present in parts of the tumor that were accessible, so far as they could be reached by cystoscopic instruments, and so far as adequate portions could be removed for histological examination. The changes indicative of malignancy occur, not, as heretofore assumed, in the "depth" where they may escape our diagnostic methods, but, first, in the epithelium, not far from the surface, either with or without areas of infiltration.

A test of the morphological criteria proved conclusively that they were trustworthy and, if adopted, led to correct diagnosis. Many of the other loosely accepted notions regarding the malignancy of papilloma *per se* were found to be fallacious. Only in one tumor out of 113 was a papilloma found to infiltrate and still retain "normal" cellular characteristics.

In short, a trustworthy pathological diagnosis and the possibility of differentiating between carcinoma and papilloma depend upon our opportunities of obtaining material and upon our ability to recognize the criteria laid down as indicative of malignancy; that the latter are present our series of tumors has definitely shown.

40 West Forty-first Street.

INTESTINAL STASIS.*

Its Causes, Prevention, and Treatment.

By Eliza M. Mosher, M. D.,
New York.

When food passes through the alimentary canal, or any section of it, so slowly that toxic substances are formed in excess of elimination, the condition is termed intestinal stasis. When such delay occurs habitually, being due to some permanent mechanical obstruction to free movement within the canal, the condition is termed *chronic intestinal stasis*.

Although obstructions which cause delay may be present in any part of the digestive tract, those not due to inflammatory adhesions are found oftenest where the peritoneal attachments are naturally somewhat short, as at the duodenojejunal junction, and the ileocecal, the hepatic and splenic flexures of the colon, and at and below the sigmoid.

It has long been known that bacteria are commonly present in large numbers in the colon, but that they may also develop in the small intestine when stasis is present, has not been as generally understood. Alkalinity, the liquid condition, and delayed movement, all favor bacterial development, while the high absorptive power of the mucous membrane of the small intestine makes the products of bacterial action a far more serious menace there than in the colon. The toxic substances thus produced in the intestinal canal when transported to the tissues of the general body by the blood and lymph, lower their vitality and render them less able to resist the invasion of disease producing germs. Possibly the ductless glands whose secretions "regulate and bring into harmonious action the various functions of the tissues," are the first to suffer under the influence of intestinal toxins. The effect of these toxins on the skin is well marked, and certainly they poison the nervous system, in some instances even to the extent, it is believed, of producing epilepsy and insanity.

What are some of the causes active in the production of chronic intestinal stasis? While unquestionably the upright posture of the body assumed by man is the primary cause, many conditions preventable and otherwise, are contributory factors in its production. Some infants are born with malformations of the intestinal tract that make stasis of its contents inevitable. Not long since, the writer saw a young woman in whom the cecum and ascending colon were on the left side; the descending colon and sigmoid on the right. In this patient the pelvic colon turned sharply upon itself, ascended to the navel line, bent abruptly downward, and proceeded on its way to the anus. A history of chronic intestinal stasis, extending back into infancy, was elicited, with constipation always present, in later life defecation without active drugging had not been possible. At the New York State Epileptic colony, Sonyea, N. Y., I found two little girls, both dements, in whom no natural arrangement of colon could be demonstrated.

Extensive mobility of the cecum which, when present, always causes more or less stasis in the small intestine, is undoubtedly congenital in many cases. A boy aged eleven years, under the writer's care, who gave a history of epileptic seizures from the age of three years, was found to have a cecum that could be displaced to a position beyond the median line of the abdomen; with this there was general enteroptosis and dilatation of the stomach and of the small intestine from pylorus to the ileocecal orifice. When the abdomen was opened by Dr. William Seaman Bainbridge, of New York city, an ileal kink was found which almost completely closed off the small intestine. The cause of this kink was a band attached to the brim of the pelvis that crossed the ileum near its junction with the cecum. A "short circuit" was successfully performed and the boy made a good recovery. During the eight months since the operation he has seemingly been well. In this case there is reason to believe that the mobility of the cecum was congenital.

Among the one hundred patients examined by the writer at the Norristown, Pa., Hospital for the Insane, four of the most pronounced suicidal patients had extensive mobility of the cecum, with dilatation of the small intestine and marked stasis. The question arises: Was this condition congenital and was it the primary cause of the insanity?

Some cases of chronic intestinal stasis in adults have been thought to be due to the persistence and thickening of certain folds of the peritoneum formed in fetal life, that commonly disappear after birth. May it not be that these result from tension upon the ascending colon, due to the inverted position of the body *in utero?* These folds were first described by Sir Arbuthnot Lane, of London; later by Jennesco and Juvare, Jackson and Treve, by whose names they are severally known.

*Read before a meeting of the seventh district branch of the New York State Medical Society, held at Geneva, N. Y., September 23, 1915.

The conditions in infancy and childhood which favor displacement downward of portions of the digestive canal are numerous. Overfeeding, the use of artificial foods which, when incompletely digested, overdistend the canal; the custom of raising the child into the sitting posture before the abdominal wall is firm enough to hold the viscera in place, trotting in this position (especially during crying), and jolting over curbs in a baby carriage, walking before the muscles of the back and abdomen have been developed by creeping—everything, in fact, in the management of an infant that repeatedly crowds the contents of the abdomen forward and downward against a weak and as yet undeveloped body wall, tends to produce enteroptosis and intestinal stasis.

Both in children and in adults those habits of posture which cause the trunk to bend upon itself at or above the navel line are even more injurious to the digestive tract than to the spine or lungs. Clothing that constricts the body at the waist line and presses the abdomen inward and downward is especially harmful. The garments in common use that do this are tight bands and stiff belts, improperly shaped and badly adjusted corsets, stocking supporters, and skirts that drag upon the abdomen. Violent exercise immediately after meals, when the stomach is heavy with food, or with the colon weighted by masses of fecal material, may cause displacement of some portion of the digestive canal.

Sir Arbuthnot Lane tells us, however, that enteroptosis does not *always* cause serious stasis, and that neither constipation nor diarrhea necessarily indicates its presence. As has already been stated, to produce the intestinal stasis that injures the general body, there must be a temporary doubling of some portion of the digestive canal that partially closes it at that point; or there must be a localized shortening of mesenteric tissue which permanently kinks the intestine and thus makes its channel so tortuous as more or less continuously to impede the onward flow of its contents. Time is thus given for toxins to be formed and absorbed from the canal in amount too great to be removed by the natural processes of elimination.

Systemic poisoning by intestinal toxins manifests itself in a great variety of ways; loss of clearness of skin, offensive breath, a continuous accumulation of gas in the digestive tract, constipation or diarrhea, *fatigue out of proportion to effort expended,* nervous sensations of an indefinite character, insomnia, especially during the later hours of the night—all the signs and symptoms, in fact, heretofore classed as indigestion, constipation, malnutrition, etc.

With its common causes well understood, measures for the prevention of intestinal stasis become self evident. Since the upright posture of the body, lack of tone of the abdominal wall, and incorrect body postures are three of its great causes, should we not as rational beings bend our energies toward their removal? If long hours in the upright posture under the action of gravitation cause sagging of the abdominal viscera, what is more simple than to take a few respiratory and other exercises on retiring, calculated to replace them, thus removing the handicap the day has placed upon their important nocturnal work? Children delight in a short play period at bed time. Let them learn to stand on the head and give them a ball to kick upward suspended above the abdomen as they lie on the floor.

Nature has decreed that both animals and men shall spend much time in the recumbent position, but the exigencies of life are tempting us to ignore this law and to permit our children to do the same. We need to practise and to teach the importance to the abdomen as well as to the body in general of long hours of rest. The digestive canal is a mechanism which in its work is peculiarly dependent upon the *time element.* Normally its processes are conducted rhythmically, and irregularity in the time of taking food upsets its rhythm. By the x ray bismuth test the intestinal time schedule has been accurately noted, and we should all do well to make our meal schedule correspond with it.

The x ray has also demonstrated that normal poise of body, standing and sitting, aids in maintaining the digestive canal in place and that habitual deviations from normal poise tend to displace it. With this fact established, is it not incumbent upon us, as physicians, to direct our efforts toward correcting the conditions in our common environment that make good posture difficult or impossible? To this end, shoes must be made to fit individual feet, especially those of children, from babyhood up. Seats must be reshaped so that they may help the body to balance comfortably in a correct position. Unfortunately most of the seats in use at present are so shaped that they either straighten or exaggerate the normal curves of the spinal column and thus prevent good posture. Gymnasium directors would do well to add to their scheme of work forms of exercise especially designed to meet the needs of the abdomen.

Auscultatory percussion. Since the position and degree of dilatation of the various sections of the alimentary canal have been found so important, it is fortunate that a reasonably accurate diagnosis can be quickly made by means of auscultatory percussion. To the ear trained to abdominal sounds it is often easier, with the patient recumbent, to outline the position of the various sections of the digestive canal and the degree of dilatation of the whole or any part of it than to detect by auscultation early tuberculous disease, pleurisy, or pneumonia. Moreover, we can check up our findings in the abdomen by giving the patient the exercises appended to this paper, and by again examining the parts with the stethoscope it is easy to note the changes in position that may have been produced. When stasis is present, these exercises, slowly repeated, will so straighten flexures and kinks temporarily as to permit an onrush of intestinal contents, the sound of which, through a stethoscope placed over the several gateways, can be likened only to the flow of water from a faucet under high pressure. The length of time this sound can be heard at a given point, the abdominal and respiratory exercises being repeated at short intervals, conveys an idea of the degree of kink present and of its situation.

When distention is *repeatedly* found to be greatest in the colon and most marked in its descending section, it is fair to conclude that the normal kink in the pelvic colon has become exaggerated. This may be due to chronic constipation, heavy fecal masses having repeatedly dragged it down, or it may have

been caused by the action of high enemata, in which the water injected accumulated and was held in this kink as water is retained in the U shaped trap of a waste water pipe. Nothing in the experience of the writer has been found so surely and permanently to injure the structure and shape of the colon as repeated high flushings without the use of a return tube.

Physicians who have not included an examination of the abdomen by auscultatory percussion in their routine of diagnostic work, have no idea of the number of patients in whom, as a sinister presence, enteroptosis may be found. Every day that it is permitted to persist, with or without symptoms, brings that day nearer when some part of the mesentery will have become shortened and thickened by "crystallization of the lines of force" (thus classically stated by Sir Arbuthnot Lane), and chronic intestinal stasis will set free its fateful brood of toxins.

Finding simple ptosis of the whole or any section of the digestive tract, what can be done to correct it? Fortunately the measures outlined for its prevention are also the means to apply to its cure. Ordinary gymnastic exercises and many of those directed haphazardly by "letter" or those sometimes given by excellent teachers of general hygiene are liable to do serious injury to enteroptotic patients. The x ray committee of the American Posture League has lately demonstrated the fact that repeated deep respirations taken in a standing or sitting posture, *without contracting the muscles of the lower abdomen,* often crowd the transverse colon downward beyond its power to return. For relief of enteroptosis, therefore, all exercises to be helpful must press the abdominal organs upward. Those that crowd them downward must be avoided. The simplest replacement exercise is the imitation of Nature's method of elevating the viscera and pushing onward the intestinal contents, viz., a long and restful yawn. This yawn movement begins with a forcible contraction of the lower abdominal muscles, a long slowly drawn breath follows with a stretching upward of the trunk and neck, then a slow expiration which, to be really restful, must empty the chest as completely as possible.

This involuntary movement can easily be made voluntary and repeated many times. The best results are obtained in the recumbent position with bent knees, but it is effective in any posture. A succession of these movements will not only elevate the digestive organs, but will carry a normally placed uterus up to its highest position. This yawn movement also pumps venous blood into the great vessels near the heart, hastens aeration and quickens the movement of blood through the capillaries of the general body, as is demonstrated by flushing of the skin.

A well fitted and properly adjusted "front lace" corset frequently maintains the needed pressure upward between pubis and umbilicus in the sitting posture, while the ordinary corset leaves this most important region unsupported. When the abdominal muscle wall is abnormally thin and weak, the viscera can be retained only by the use of a belt[1] which *elevates* the abdomen—not simply presses it backward, from pubis to umbilicus.

[1] A Brooklyn firm manufactures to order a belt, designed by the writer, which serves this purpose well.

TREATMENT.

Intestinal stasis patients need to eat and sleep by the clock as nearly as possible; use meat sparingly and drink water plentifully between meals. Little, if any medicine is needed. Sometimes a digestive, a mild laxative, or a general tonic has to be given for a time. Russian oil or one of its substitutes should be taken without stint, for, since it is neither a medicine nor a food, it can be used without restriction. When bands or kinks are found, and fortunately these are present in not more than ten per cent. of enteroptotic patients, the case becomes one for surgical consideration. Here the x ray does its great work, giving more minute and accurate information regarding the conditions to be dealt with than can otherwise be gained.

Unhappily, as a profession we are still in the twilight stage of operative treatment for the relief of chronic intestinal stasis. Lane, Bainbridge, Bloodgood, and others are lighting the path, but their work, though brilliant, only makes clear the difficulties to be encountered, and a need for the skill that comes only through familiarity with the complex conditions so commonly found, and a knowledge of the best methods for dealing surgically with each.

EXERCISES TO AID DIGESTION, PREVENT CONSTIPATION, AND STRENGTHEN THE ABDOMINAL WALL.

I.

Lie on the back (bladder empty and knees bent). Gently stroke the abdomen downward six times along the inside of the left hip, from ribs to pelvis.

II.

Stroke three times across the abdomen on the navel line from the top of the right hip to the top of the left, then downward as in Exercise I.

III.

Draw the lower abdomen forcibly inward by muscle contraction (not by breath), and imitate the movement involuntarily made in taking a long restful yawn—breathe in slowly all the air possible, stretching the trunk and neck upward, then as slowly breathe out all the air taken in. Repeat six or eight times. This exercise can also be taken in the sitting or standing posture and should be repeated often when enteroptosis is present.

IV.

Forcibly draw in the lower abdominal wall (not by breath but by muscle contraction), then raise it and hold long enough to count ten. Do this three times. Rest and repeat.

NOTE.—If the abdomen is distended by gas, insert a small tube (the rectal point of a syringe) into the rectum before beginning the exercises; if retained, it will let out the gas as fast as it is carried down. Never apply pressure below and to the inside of the right hip (region of the appendix).

These exercises should be taken by every one on retiring, to overcome the sagging of abdominal organs due to the standing and sitting posture. They may be repeated half an hour or more before meals, if indigestion and gas are present.

GALEN HALL, BROOKLYN.

RECTAL ANESTHESIA.

A Demonstration of Gwathmey's Method,

By William M. Johnson, M. D.,
New York,
House Surgeon, New York Skin and Cancer Hospital.

Rectal or colonic anesthesia was of no practical importance until Gwathmey, after extended experiments by himself and collaborators, perfected the oil ether colonic anesthesia. He first presented a paper before the Seventeenth International Congress, at London, August 6, 1913, calling attention to the superiority of this method and reciting the animal experiments of himself and coworkers.

The first successful clinical demonstration of oil-ether anesthesia was held at the People's Hospital, New York, September 27, 1913, upon a patient of Doctor Rothenberg. Since this time the technic has been slightly modified and perfected, and those who have given the matter any thought, or the method a trial, are quite enthusiastic, so that now it is used by a large number of surgeons in all parts of the country. As an instance, to demonstrate the confidence of the man in his own method, I will just say that Doctor Gwathmey recently had to undergo some surgical operation and had one of his confrères give anesthesia by this method. Both the anesthesia and the operation were successful. In a recent conversation, he reports about 2,000 cases with no fatalities.

In the hospital with which I am connected, I have supervised over fifty cases of oil-ether anesthesia, with absolutely no untoward effects. Most of these cases were on the service of Doctor Bainbridge. In comparing these cases with the other methods, namely, the vapor and drop methods, lung irritation, post-operative nausea, and vomiting seemed less. Fright and mental shock were certainly much less. The method is liked by the patients. I have repeatedly had them say, on return from the operating room and to consciousness, "When will I be operated on?" More than once, in extremely nervous patients, who particularly dreaded the anesthesia, I have had the oil-ether mixture administered without their knowledge, they thinking they were getting only a bowel irrigation. They would go off into surgical narcosis, be taken to the operating room and returned, with no knowledge of what had occurred. This eliminates the ordeal of the patient's sometimes facing the surgeon and assistants, with the gruesome appearance of the operating room, and the much dreaded ether mask; thereby abolishing fright and mental shock. The method thus carried out would seem to obviate the necessity of nerve blocking, or Crile's anociassociation, in general anesthesia.

The patients are prepared as for vapor anesthesia, with the exception that the rectum must be absolutely free and clean, in other words, in the best possible condition to absorb the mixture. It is our custom to order a cathartic dose of castor oil at two p. m. on the day before the operation. At night the patient has (after the oil has acted) colon irrigation until the water returns clear. In the morning one or two colon irrigations are given, until the water returns clear. Two hours before the operation, five to fifteen grains of chlorotone is given per os; thirty minutes before the regular anesthesia is given the following is administered:

Paraldehyde, ...3ii to iii;
Olive oil, ...3ii;
Ether, ...3iii to iv.

This is given by a competent nurse, and allowed to flow very slowly, about one ounce escaping each minute, having the patient in the Sims position. It is important to have the patient in a dark room, and free from noise such as loud talking, etc. If in a ward, the bed should be screened. At this time, the patient also receives one sixth to one quarter grain of morphine, together with 1/150 grain of atropine subcutaneously, remembering that hyoscine, grain 1/200, in addition to the morphine, acts better with alcoholics. These agents are synergistic and should always be chosen according to their indication. The patient must not be disturbed in any way until surgically unconscious (regardless of the surgeon's hurry), which will require from fifteen to thirty minutes. After about four minutes, the odor of ether will be noted on the patient's breath. The ether does not separate from the oil, until warmed and vaporized by body temperature, when it is taken up by the intestinal mucosa, through the hemorrhoidal veins, transmitted to the liver, thence to the heart, and finally to the lungs. The absorption by this method is slow and uniform; the patient absorbing about two ounces an hour, less than any other save the intravenous, which is about one and one half ounce an hour. The vapor and drop method are variously estimated at from three to six ounces an hour. The dose is determined by the age, weight, and habits of the patient, about one ounce of ether being required for each twenty-five to thirty pounds body weight. When paraldehyde is used, this may be lessened, but we never give over six ounces of a seventy-five per cent. oil-ether mixture to adults, regardless of weight. Children require only from fifty to sixty per cent. of ether, and when below nine years of age, no preliminary treatment.

This method differs somewhat from the respiratory, inasmuch as the ocular reflexes should never be abolished, neither should stertorous breathing be allowed to continue. *These are danger signals!* If they occur the indication is to withdraw from one to two ounces, or all of the mixture, massage the bowel from left to right immediately over the transverse colon, and irrigate with cold water. If the patient seems to be coming out, keep mouth and nose covered, when they will rebreathe and quickly go back into a smooth, easy surgical narcosis. If the patient is getting too much, the nose and face may be left uncovered. The tongue and jaw should be carefully watched in this, as in any other general anesthesia. At completion of operation, the colon should be irrigated, the transverse colon being massaged from left to right. This may be accomplished through rectal tubes, which have been left in place but clamped off, while dressings are being applied and before the patient is removed from the operating table.

The advantages of this method are the safety and ease of administration, without complicated apparatus, the only things required being a rectal tube, with funnel, and a Gwathmey irrigating tube. It is specially indicated in all operations on the head.

neck, throat, or chest, the obese alcoholic, and aged patients on account of lessening bronchial irritation. Contraindications are any disease of the intestines, operations on the pelvis, and in general laparotomies, on account of gaseous distention. However, with competent assistants to hold back the intestines, this may be accomplished, and not a few celiotomies are being performed under this method of narcosis. When the method is better understood, it will be the method of choice in suitable cases.

301 East Nineteenth Street.

ANESTHESIA.*

Suggestions Bearing upon Its Standardization for Teaching Purposes,

By P. J. Flagg, M. D.,
New York.

Any man who administers anesthetics is at some time or other called upon to impart his knowledge to others who are being initiated into this special branch of the practice of medicine. In order to get close to the student, we must reduce anesthesia to its simplest terms. We must explain the subject in simple words before we allow ourselves to become technical. It is perfectly easy to lose our audience by employing unfamiliar terms, or terms which mean little to the average man. For example, take the term, "vapor tension." What does that mean to the man whose last intimate acquaintance with physics was five or more years ago? The incidental employment of such a term may pass, but if we proceed to make use of it to illustrate or compare, our audience is left behind. According to the general meaning of the term, teaching is not an effort to ventilate our opinions, but to impart them to others, and this can be done only by being sure that the terms which we employ are perfectly familiar to all.

Men who are specially interested in a particular subject are prone to ignore or slur over the wearisome and simple fundamentals which brought them to their present point of view. As a consequence, the student who has missed the fundamentals cannot grasp or appreciate that which is being placed before him. In teaching the art of anesthesia, we are prone to depend upon the information which the student is supposed to have gained in his materia medica and therapeutics. In describing the signs of anesthesia, we speak of them as occurring during certain stages. We speak of the excitement of the first stage, of the dilated pupil of the third stage. The term, preanesthetic stage, is often heard. It is said that such and such an operation can be done in the preanesthetic stage, during which the patient *is* yet *is not* anesthetized. We have been brought up upon the term, surgical anesthesia. This is thought to be a very definite stage, in spite of the fact that anesthesia sufficient for the opening of a boil is a very different thing from that which is needed for a laparotomy. If we can establish a classification of the stages of anesthesia which can be used as a basis for all anesthetic agents administered by all methods, we may speak to the uninitiated and to one another in a manner to be understood.

*Read before the New York Society of Anesthetists, May 26, 1916.

The classification of the stages of anesthesia which follows might be called a clinical classification, or a classification combining the findings of the physiological laboratory and the operating room. This classification is not only easily grasped, but is equally easy to retain and demonstrate.

GENERAL, LOCAL, AND SPINAL OR MIXED ANESTHESIA.

These form the three primary divisions, and are based upon the extent to which the nervous system is anesthetized. In general anesthesia both the central and the peripheral nervous system is anesthetized; in local anesthesia only the peripheral nervous system is involved. In mixed or spinal anesthesia, part of the central nervous system (the spinal cord) and the peripheral nervous system are under the influence of the anesthetic.

We recognize two degrees of general anesthesia, complete and incomplete. These degrees are characterized by the presence or the absence of complete muscular relaxation. In a complete general anesthesia, the relaxation is universal; in an incomplete general anesthesia, relaxation is partial or absent.

A complete general anesthesia consists of three

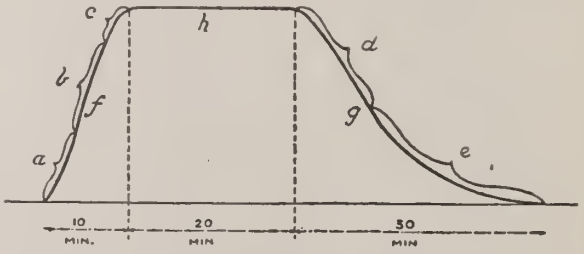

Fig. 1.—Curve of complete anesthesia; *a*, excitement; *b*, rigidity; *c*, relaxation; *d*, return of reflexes; *e*, return of consciousness; *f*, induction; *g*, recovery. (Courtesy, J. B. Lippincott Co., *Art of Anesthesia.*)

stages: 1. Induction; 2, maintenance; 3, recovery. These three stages may readily be represented by a curve (Fig. 1). They are present and demonstrable with all anesthetic agents and with all methods which yield complete muscular relaxation.

The stage of induction begins with a loss of consciousness and ends with the onset of complete relaxation.

The stage of maintenance begins with the completion of relaxation and continues until the administration of the anesthetic is permanently reduced with a view of bringing the patient back to consciousness.

The stage of recovery begins when the administration of the anesthetic is permanently reduced with the view of bringing the patient back to consciousness, and ends with the return of consciousness. Induction anesthetizes the patient; maintenance keeps him anesthetized; recovery returns him to consciousness.

The stage of induction consists of three periods: 1. Excitement; 2, rigidity; 3, relaxation.

The stage of maintenance is not subdivided, but two varieties may be observed: *a*, Constant maintenance; *b*, variable maintenance.

Constant maintenance is obtainable only where a special device is employed which will deliver to the

patient a large volume of ether vapor of a definite percentage under pressure; such an apparatus as the Connell anesthetometer, for example.

All other methods of anesthetization yield a *variable maintenance.*

The stage of recovery is naturally divided into two periods: 1. The return of the reflexes; 2, the return of consciousness.

The end of the first period comes about in the operating room, while the patient is under the immediate supervision of the anesthetist. The end of the second period usually takes place after the patient has reached his bed, and has passed into the nurse's care.

Two types of recovery are easily recognized: 1. Recovery by crisis; 2, recovery by lysis.

The first type is best characterized by the recovery which we see in a gas oxygen anesthesia; the second is the usual recovery seen in a prolonged ether anesthesia.

This very simple classification of the stages of anesthesia may be used as a basis for the discussion of any anesthetic agent administered by any method.

Where a detailed study is desirable, we may attack the subject by considering the evidences, the causes, and the control of the periods of excitement, rigidity, and relaxation; for example, the causes of the period of excitement:

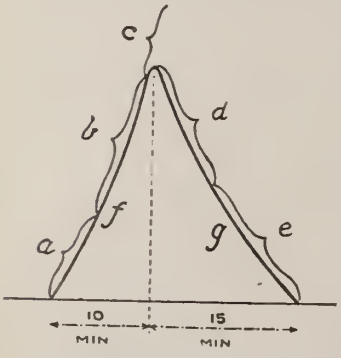

Fig. 2.—Curve of incomplete anesthesia; *a*, excitement; *b*, rigidity; *c*, relaxation; *d*, return of reflexes; *e*, return of consciousness; *f*, induction; *g*, recovery. (Courtesy of J. B. Lippincott Co., *Art of Anesthesia.*)

Physiological effects of ether.

Lack of preparation or faulty preparation.

Alcoholism.

Temperament.

Overconcentration of the anesthetic.

Excessive smoking.

Sexual.

Previous unsatisfactory anesthesia.

Nasal obstruction, almost the rule in children.

Failure to understand what anesthesia means.

Excessive fear.

Remarks which the patient hears before losing consciousness.[1]

The curve which represents complete general anesthesia forms a basis upon which we may become familiar with the idea of vapor tension or anesthesia by the percentage method.

Where such a classification is employed, the signs of anesthesia may be definitely charted. We may speak of the behavior of the pupil under ether during the stage of induction, maintenance, and recovery with the assurance that the time specified will not be misunderstood. We may speak of the complicating effects of morphine upon the same basis. The detailed effects produced by rebreathing with various anesthetics are thus quite easily identified.

It will be seen from the foregoing that muscular relaxation is a test of the worth and efficiency of the general anesthetic. An anesthetic which will not bring about good relaxation, even though it is safe, can never be other than a method of choice in selected cases. We must not forget that the anesthetic is but a means to an end, not an end in itself; that the inexperienced surgeon, the man who does not object to rigidity, will not learn to do good work, that the experienced surgeon cannot do his best work in the face of muscular rigidity.

In upholding the cause of relaxation, we do not intend to overshadow *safety,* immediate or remote. We speak of this quality as *an* essential, not as *the* essential. We do not intend to discountenance gas oxygen or to exalt chloroform. What we wish to do is to emphasize the necessity of relaxation where indicated, and to point out the fact that the routine anesthetic must be capable of bringing about this effect.

In conclusion, then, we offer this clinical classification of the stages of anesthesia in the hope of simplifying the technical subjects which we present for the consideration of one another.

RABIES.

Clinical Report of an Unusual Case,

By Miley B. Wesson, B. S., M. D.,
El Paso, Texas.

During the fall of 1915, there was an epidemic of rabies among the dogs in Juarez, Mexico. On October 22nd, a large, black dog, afflicted apparently with a maniacal form of rabies, bit two Villa soldiers, and when chased by them, escaped via the Stanton Street bridge to El Paso. The following day, Gonzales Marterine, Mexican male, aged three years, of 1008 South Stanton Street, while at play in the street, was attacked and badly bitten on the cheek by a stray, black dog that escaped, going north. A black dog was reported about this time to have bitten a lot of dogs in the neighborhood of North Stanton and Nevada Streets, about a mile north. Among the dogs implicated in the fights was a white poodle. On November 19th, a small, shaggy, white dog showed the maniacal form of rabies, in this neighborhood, and bit a seven year old boy and a six year old girl, both of whom were immediately treated at the El Paso Pasteur Institute. The dog was captured, sent to a veterinary surgeon's hospital for observation, and died of typical rabies. All of the stray dogs in the vicinity were at once killed and the pets tied up; and no other dog in that section acquired rabies.

On the evening of November 7th, the Mexican child, Gonzales Marterine, was carried to Doctor Strong's office, where I saw him. The child appeared irritable, anxious, and had a peculiar hunted look in his eyes; had a sighing respiration, difficulty in breathing; the parents said that he had been well up to two days before, when he was noticed to be feverish and thirsty, then dysphagia developed, and the child would cry at sight of water and push the glass away; sleep was broken, the child often starting up as from a bad dream. This dysphagia, and

the fact that when one attempted to blow on the child's neck he would go into convulsions, was responsible for the seeking of medical aid.

Examination showed a mentally alert, nervous child, free only a few minutes at a time from muscular twitchings; eyes were bright, tendon reflexes not exaggerated, pulse was quick, regular, and of small volume; the grip of both hands was fairly good, though that of the left was weaker. The child seemed uncertain on his feet when attempting to walk, and limped with the left leg (1). The parents said there had been a profuse flow of saliva, though there was no evidence of it at this time. The bite caused a large abrasion on the left cheek, and this was not irritated, but looked like an old eczematous rash. Quinine, according to the method of Moon(2), was prescribed. A similar case treated this way two years before, proved fatal without convulsions (3). This child succumbed before treatment was instituted, however, as the druggist held up the prescription for verification—on account of the dose. Hospital care was refused, and the father carried the baby away to an unknown address in Juarez—as I learned after several hours' search.

During the night the dysphagia grew rapidly worse, and the following morning about eight o'clock the father started to walk to the office with the baby in his arms. On the way the child had a slight convulsion and died instantly.

This case is reported because of the apparent connection between the various rabid dogs, the short time intervening between the bite and the death of the child, and the mode of death.

THE CLINICAL THERMOMETER AS A CARRIER OF INFECTION.

By L. Martocci-Pisculli, M. D.,

New York,

Chief of Clinic, Gynecological Department, Harlem Hospital Dispensary.

Like many other physicians, the writer has for many years been impressed with the inadequate way in which most general practitioners, chiefly the busy ones, make use of the clinical thermometer. This article is not intended as an indictment; indeed, it is more of a confession which, however, the writer believes should be honestly, if not contritely made by every busy physician.

While making several calls in succession, most physicians content themselves with rinsing their thermometers in cold water and wiping them dry; then using them on one patient after another. Very often they will see in one trip, say, a diphtheria, a typhoid, an influenza, and a pneumonia patient. In most cases we do not find a disinfectant ready at hand nor do we usually spend ten or fifteen minutes disinfecting the thermometer.

As the writer had been one of the sinners, it has occurred to him that the physician might carry infection from one patient to another. It is true that most practitioners carry more than one thermometer, one usually being for rectal use, but even so it is quite likely that the germ of one disease is carried on the innocent looking piece of glass and planted on receptive soil.

Of course, it is difficult to say exactly in how many cases disease is actually transmitted by means of the clinical thermometer. In order to determine, first, whether germs are actually carried in this fashion, and, secondly, whether they can be recovered and grown in culture media, the writer has undertaken a series of examinations, the results of which form the burden of this article.

A number of thermometers were taken from various physicians who had washed them in running water after using them on patients. Several dozens were stained and examined. Then several thermometers taken at random were washed and the fluids used to recover the germs. The results were startling. The writer finally went to the board of health research laboratory in New York to investigate under the supervision of competent bacteriologists. In this instance cultures were made both on serum and broth and the germs were grown.

At my suggestion, and through the courtesy of Doctor Dickson, resident physician of the Willard Parker Hospital, Miss E. Valentine carried on the investigation under the immediate direction of Professor William H. Park.

The thermometers were taken from diphtheria patients of the Willard Parker Hospital. Some were washed and dried with sterile gauze, others were only dried in the presence of Doctor Dickson. Only one thermometer came from a private patient suffering with bronchopneumonia. Two series of investigations were carried out, one on March 1, 1916, and the other on March 10, 1916.

First Series, March 1, 1916.

Disease	Method of cleaning thermometer	Serum Cultures	Broth Cultures
1. Diphtheria	Washed in water and cleaned with sterile gauze	Staphylococcus pyogenes aureus Pneumococcus	Staphylococcus pyogenes aureus Pneumococcus
2. Diphtheria	Washed in water and cleaned with sterile gauze	Staphylococcus pyogenes aureus Pneumococcus	Staphylococcus pyogenes aureus Pneumococcus
3. Diphtheria	Cleaned, not washed	Staphylococcus Pneumococcus	Staphylococcus Pneumococcus
4. Diphtheria	Cleaned, not washed	Pneumococcus	Pneumococcus

Second Series, March 10, 916.

Disease	Method of cleaning thermometer	Serum Cultures	Broth Cultures
1. Broncho-pneumonia	Washed in water and cleaned with sterile gauze	Diplococci	Diplococci
2. Diphtheria	Washed in water and cleaned with sterile gauze	Diplococci	Diplococci
3. Diphtheria	Washed in water and cleaned with sterile gauze	Diplococci Diphtherialike bacilli	Diplococci
4. Diphtheria	Not washed, but cleaned with sterile gauze	Negative	Staphylococcus A few pneumococci
5. Diphtheria	Not washed, but cleaned with sterile gauze	Staphylococcus Diphtherialike bacilli	Few diphtheria-like bacilli

The tables show the presence of pathogenic microorganisms on thermometers after they have been washed and cleaned with sterile gauze. All the thermometers which were stained and examined microscopically revealed the presence of bacteria, some corresponding to the disease in which the thermometers were used. It is reasonable to suppose, therefore, that if cultures had been made, the same germs would have been found as in the plain microscopical examinations.

The results speak for themselves. They simply

emphasize what every physician has often suspected. They are reported here merely to establish, experimentally, the fact that the thermometer is a very dangerous carrier of microorganisms, and the haphazard way of cleaning it and passing it from one patient to another without thorough disinfection is fraught with the greatest possible danger.

There is no doubt that diseases like diphtheria, pneumonia, meningitis, tuberculosis, influenza, acute follicular tonsillitis, and syphilis, can be carried from patient to patient.

Since the virus of acute anterior poliomyelitis is found in the mouth and feces, it is not unlikely that this disease too may be transmitted in this way.

Before finishing, it may not be amiss to quote Professor W. H. Park. The words of so eminent an authority carry sufficient weight on the subject, and I need only express my thanks for his kind assistance and permission to quote him: "The results obtained both from the stained thermometers and the cultures are very interesting and surprising. It was theoretically known that the thermometers, as used by private physicians, without hospital facilities, were germ carriers, but it had not been demonstrated practically by the microscope and cultures. This shows without a doubt that live pathogenic germs remain on the thermometers not properly disinfected, capable of spreading infection. The demonstration is quite remarkable."

CONCLUSION.

1. All thermometers taken from patients carry live pathogenic germs. They are, therefore, disease carriers.

2. Washing them in water and wiping them dry in no way destroys the germs or even reduces the danger of carrying infection. Cold water hardens and so fixes the mucus with the containing bacteria on the thermometers.

3. It is absolutely imperative to disinfect the thermometer after using it on a patient and in every single case, no matter how insignificant the cause of his fever may appear today—tomorrow you may find that you have used your thermometer on a typhoid or pneumonia patient.

4. Physicians must either devise some method of disinfecting the thermometer while carrying it in its case, or spend a few minutes in each patient's house to disinfect it.

235 Second Avenue.

SOME NOTES AND A PROPHECY.

By G. Arbour Stephens, M. D. (London),
Swansea, Eng.
Honorary Physician, Royal Cambrian Institution for the Deaf.

In the *Lancet, British Medical Journal,* and the *Dublin Journal of Medical Science,* I have already drawn attention to the value of subcutaneous injections of distilled water in subacute or subchronic conditions, such as syphilis, rheumatism, gonorrheal rheumatism, inflamed glands, and appendix cases.

The most remarkable case was that of a man suffering from syphilis and gonorrheal rheumatism, who had not worked for months, whereas after three injections of ten c. c. distilled water he resumed his occupation.

A good case was that of a boy who had injured his elbow, with a resultant ulcer which refused to heal, even after grafting, until he had been injected with distilled water, when it closed up rapidly.

Interesting results have taken place in cases of chronic ear discharge, for in several cases after six weekly injections the quantity has been reduced to nil, and the offensiveness entirely removed.

In subchronic dermatitis in a man aged fifty-six years, where the front of the chest and arms were covered by a moist eczematous condition, the biweekly injections produced a splendid result.

Cases of recurrent pain and swelling of the appendix have responded well; in one young man, aged twenty-one years, the pain recurred every six weeks, but after six injections, he has been quite free for a long period, and *mirabile dictu,* the constipation, which was a source of great worry, has also disappeared, there being no necessity to take medicine of an aperient nature.

I am now carrying out trials in connection with plumbism, and in three cases the results have been satisfactory, but I want further experience.

The rationale of the treatment is, I think, that distilled water, which has a high surface tension, when brought into contact with the leucocytes, causes osmosis outward, whereby the antibodies therein are rapidly mobilized; also the leucocytic diapedesis is stimulated so that the scavenging qualities are improved.

The specific vaccines employed hitherto have also aimed at this improvement of the scavenging department, but unless the vaccine was absolutely correct, the result was poor, hence the weakness of specific therapy. The treatment by means of subcutaneous injections of distilled water is *naturalistic,* whereby Nature is helped to recover herself, the natural formation of antibodies as well as their mobilization being encouraged.

The advantage of this method is, that there is no danger as in specific vaccine treatment when the vaccine is not correct. For this reason I venture to prophesy that the treatment by subcutaneous injections of distilled water ought to be of great value in leprosy.

This is a disease due to some poison whereby bacilli grow in the system, but where the antibodies are not present in sufficient numbers to perform their work satisfactorily.

If we can, by distilled water, help in their mobilization, the result ought to be satisfactory.

I have written to a few medical men in charge of leper settlements in the hope that they would give it a trial.

It may interest readers to know that James Howell, author of *The Familiar Letters* and a friend of Harvey who demonstrated the circulation of the blood, wrote, on April 10, 1622, from Trevere: "We are now in North Holland, where I never saw so many, among so few, sick of leprosy; and the reason is, because they commonly eat abundance of fresh fish"!

Dietetics, Alimentation, and Metabolism

Food and Food Preparation, in Health and Disease

FOOD AND EFFICIENCY.

By Martha Tracy, M. D.,
Philadelphia,
Professor of Physiological Chemistry, Woman's Medical College of Pennsylvania.

(*Continued from page 749.*)

As investigation proceeded and the respiration calorimeters for animals and for man were built and perfected, it was in due time shown that *carbohydrates* and *fats* taken as food by a living animal or man, are burned in the body and produce almost the identical amounts of carbon dioxide and water, and liberate the same amount of heat as is produced by that same carbohydrate or fat in the combustion calorimeter.

For proteins the figures were a little different, because in the animal this nitrogen-containing material is not as completely burned as in the bomb calorimeter, and some of the fuel value is lost, in such substances as urea, uric acid, creatinine, etc., which are excreted in the urine, and which are still combustible, though the body cannot burn them further.

It is also found that a little of the carbohydrate and fat and protein eaten is not digested and absorbed from the gastrointestinal tract, and so the material which actually gets into the blood and is carried to the muscles and other tissues where it is oxidized, is a little less than that actually derivable from food put into the mouth. We speak of this small amount as that material "lost in digestion." To express the actual fuel values in the body we subtract these small differences from the figures obtained by the bomb calorimeter and say that "one gram of carbohydrate has a physiological value, a fuel value to the body of four calories; one gram of fat—a value of nine calories"; one gram of protein—a value of four calories.

Carbohydrate	120 cal. to the oz.
Fat	270 cal. to the oz.
Protein	120 cal. to the oz.

With these small differences thus accurately accounted for, the remarkable fact is established that food substances yield energy in the form of heat and mechanical work in the body almost exactly to the extent to which they yield energy in form of heat, transformable into work, when they are burned in any furnace. The human body then, like a locomotive, is an engine which cannot run without a fuel supply.

The human engine, however, differs from the locomotive in some striking particulars. In the locomotive there is one firebox into which the fuel is put, and to this chamber oxygen is supplied in proper draughts of air, so that the combustion or oxidation takes place. The heat produced can be utilized to raise the temperature of water to the boiling point and so generate steam, which by suitable mechanical contrivances is transformed into various forms of mechanical work, or in other engines, into electricity and light.

In the living animal body there is no single firebox where the fuel is burned. The stomach and intestine merely serve to receive the fuel supply and change the compounds so that they can pass in form suitable for use by the tissues through the walls of the intestine into the blood as it circulates through the small vessels of these organs.

But the blood is not the firebox either; it merely distributes the fuel, carries it throughout the body to all the different organs and tissues, and in the microscopically tiny cells that make up these body tissues the fuel is actually used—the oxidations that constitute the life processes take place. So each cell, but especially the cells of the muscle tissue, is a minute firebox, or combustion furnace in which the fires of life occur.

As in any other furnace, to be sure, these fireboxes must be kept clean, so that the draughts of oxygen brought also by the blood from the air breathed into the lungs, can be effective in promoting the oxidations; and the "ashes" or waste products must be continually removed also by the blood stream, so that the grate and flues shall not become choked and interfere with proper continuance of the combustion.

Another striking difference between the locomotive engine and the animal engine is that the latter, the animal body, is constructed of the same sort of material as its fuel—chiefly of the protein or nitrogenous part of its fuel. This is very important. When coal is not supplied to the locomotive engine the fire soon goes out and the engine stops running. When food is not supplied to the animal body, the fires will burn for a time supported by the fuel still remaining in the circulating blood; and when this is gone fuel which may be stored up in the liver is thrown out into the circulation and so distributed to be burned. When this is gone the fat, which is stored in different parts of the body —everywhere under the skin, and as pads and cushions around the organs—will be drawn into the circulation and distributed to the cells to support combustion. In this condition of starvation, as we call it, the animal grows thin; it is burning up its own tissues in a way that the locomotive engine cannot do.

After the fatty tissue is burned the essential cells of the organs begin to be destroyed, and the muscles themselves become smaller and weaker as the material of the cells is dissolved in the effort to keep up the fire and combustion in the heart muscle. The animal engine, then, provided that water is supplied—and it is a very interesting and important fact that for cellular combustions the substances must be dissolved in water in order to burn—can continue its activity without food, long after the locomotive engine has—for lack of fuel—ceased to run.

Furthermore, the animal engine differs from the locomotive engine in that *it can repair itself.* The locomotive cannot mend the piston rod if it

breaks, nor replace the bits of steel that are continually wearing off from the moving parts. The normal animal engine is doing this very thing every day and every hour. Always the substance of some of the cells is wearing out, disintegrating, and this broken down material is being swept away in the blood stream to the excretory organs, and always new material brought in the food supply is being built again into the cells, repairing the old, or building new to replace those worn out.

When the animal is young, not only is this repair and replacing of cells going on, but actual multiplication of cells is taking place also, so that the animal is growing in size.

The food supply of the man, then, means more than the mere fuel to furnish energy for heat and work; it must include also building material for repair of cells and for growth of new cells.

It is at this point that the protein foodstuffs become of such fundamental significance. I noted a few moments ago that the body is composed of substances similar to those comprising the food supply, especially the protein part of the food supply. The protein foods are those containing nitrogen, phosphorus, sulphur, and iron. The protein cells are repaired and new ones built with material that has nitrogen, phosphorus, sulphur, and iron in it, and so some protein food must be supplied. Pure carbohydrates and fats do not contain these elements, and cannot possibly take the place of this kind of building material.

To be sure, a little carbohydrate and a little fat are used in building new cells, but by far the greatest part of fat and carbohydrate food serves as fuel only. These, then, are often referred to as fuel foods, while proteins are essentially tissue building foods, only the protein excess serving as fuel.

II.

PROTEINS.

All proteins are not of equal value as tissue building materials. Chemists have learned that the proteins are very complex substances, which by appropriate means may be broken into many fragments or simpler compounds called aminoacids, and these foodstuffs are so broken up in the process of digestion. There are many of these aminoacids and we often refer to them in the words of the Germans as the "building stones" of the protein. Their names, leucin, tyrosin, valine, glycine, lysin, tryptophan, etc., mean little to one who is not a chemist, and to such a one it is simpler to think of a protein in the metaphor suggested by Professor Lusk as a word spelled with many letters. The proteins of which a muscle cell is built are different from the proteins that build liver cells. Different proportions of the building stones are needed to construct them.

Some of the different kinds of protein are: Albumin, found in meat, milk, and egg white; globulin, found also in meat, egg white, and cereals; gelatin, prepared from tendons and bones; vitellin from egg yolk; gliadin from wheat; zein from Indian corn; and there are many others; and there are several kinds of protein in each cell.

Continuing our metaphor—to construct globulin for repairing a muscle cell we must supply the letters g-l-o-b-u-l-i-n. If we take gelatin as our only protein food we cannot do this. We shall have the g, i, n, one of the l's, but no b or u or o. Even if we take twice as much gelatin, which will give us the two l's, it will still leave us lacking b and u and o. So not only must we have *some* protein food, but we must have protein food of the *right kind*, or of *enough different kinds*, to furnish the letters we need to spell our special cell words. If the body does not receive in the food supply enough proper protein to supply its cells day by day, it will gradually lose weight and die.

There are proteins in vegetable foods. I have mentioned gliadin and zein, but they are not as abundant as in animal foods, and, furthermore, the vegetable proteins are less like human proteins, and must be taken in larger amounts to supply the body need than is necessary when the protein supply comes from the tissue of other animals, as in milk, eggs, meat, etc. An experiment showed, for example, that thirty grams of meat protein a day would protect a man from loss of his own cell protein, but that if milk protein replaced the meat thirty-one grams were necessary, or fifty-four grams of bean protein, seventy-six grams of bread protein, or 102 grams of Indian corn protein, to afford the same protection or saving of body tissue.

This difference of value as building material characteristic of certain proteins has been wonderfully demonstrated in the results obtained by Mendel and Osborne,[1] in feeding experiments with white rats. These animals are chosen for such experiments because their span of life is short, the rat reaching maturity or adult life in sixty days, and living in all about three years. Thus it is comparatively simple to watch the effect of diets through the infancy, youth, adult life, and old age of the animal. Also the animals become very tame and easy to handle, and they eat readily the food mixtures offered, palatability appearing to have little or no influence. Food mixtures were therefore prepared containing suitable and sufficient amounts of carbohydrates, fats, and inorganic salts, and to which different pure proteins could be added at will, in order to study the effect upon the maintenance of body weight, and the growth of the animal.

According to the careful studies of Donaldson, a normal young white rat fed on an adequate diet, containing a mixture of different proteins, grows at a rate which in forty days will give a body weight of forty grams, in eighty days a weight of 125 grams, and in 120 days a weight of 190 grams. Here the proteins in the food supply all of the letters necessary to spell the protein words of the rat's cells, and construction of tissue proceeds at a normal rate.

When, however, young rats were fed for forty or fifty days on a diet mixture that contained gliadin prepared from wheat as the only protein substance, *no gain whatever* occurred in the weight of the animal during this period, though *maintenance* of weight was fairly good. A rat weighing about ninety-five grams at the beginning of the experimental period showed the same weight after forty days of this diet. One or more letters

[1] Osborne and Mendel: Feeding Experiments with Isolated Food Substances, *Bulletin 156*, Carnegie Institute, of Washington.

of the protein words needed by the rat were lacking, and no new tissue could be built. About the fiftieth day the diet was changed and a mixed food containing other proteins, including a little milk, was given. At once the animal began to grow at eighty days weighing 170 grams, and at 120 days 220 grams. All the nutritive needs were now supplied, and there was no longer any hindrance or failure to construct new tissue protein.

Analysis of this protein gliadin showed that the chief difference from other adequate food proteins lies in the entire lack of the aminoacid lysin. Apparently without this aminoacid, though the animal body is *maintained* without loss, *no growth* can take place.

In another experiment reported by these authors (*Journ. Biol. Chem.* xviii, 1, 1914) the food mixture for certain periods contained *gelatin* as the only protein, and in these periods there was *not even maintenance* of body weight, but a steady and *striking loss*. In alternate periods a milk protein mixture was fed, and always there was prompt recovery of the loss and even a slight gain. Finally, at the end of 367 days a diet of milk and mixed food was given and prompt and continuous growth followed.

The most recent investigations along these lines (Osborne and Mendel, *Ibidem*, xxvi, 1, 1916) have confirmed and strengthened the suggestive results of the earlier work. By most carefully controlled experiments in which rats of the same weight were used and the conditions managed so that identical amounts of the food mixtures were taken by the animals, it has been conclusively shown that "to produce the same gain in body weight fifty per cent. more casein than lactalbumin was required, and of edestin (protein from hemp seed) nearly ninety per cent. more," and, further, "that the addition of cystine (an aminoacid containing sulphur) rendered the casein so much more efficient for growth that, on the average, eighteen per cent. *less* protein produced 12.5 per cent. *more growth*."

Thus it is conclusively shown that not only *some protein*, but the *kind of protein* taken in the food is of great significance in nutrition.

It is suggestive to note in connection herewith, that the disease known as pellagra, which has mystified investigators for many years, appears, according to the evidence brought forward by recent experiments in the South, to result from disturbance of the nervous system due to lack of adequate protein in the diet.

(*To be continued.*)

The Effect of Diet on the Teeth is often overlooked by the physician in outlining a dietary. Too much soft food, especially starches and carbohydrates, tends to help decay with later impairment of mastication. It is a good rule to insist on the daily use of some hard foods, especially with children, in order to strengthen the jaw muscles and help the teeth develop as well as keep them clean. Fresh fruits and vegetables, hard crackers, and bacon rind are valuable for this purpose. Their preparation is a simple matter and once started their habitual use is easy.

Rules and Diet for Goitre Patients.—Albert J. Ochsner (*Annals of Surgery*, October, 1916) formulates the following rules for goitre patients: 1. You should avoid all excitement or irritation, as attending receptions, shopping, church work, and politics. 2. You should get an abundance of rest, by going to bed early and taking a nap after luncheon. 3. You should have an abundance of fresh air at night; consequently, you should sleep with wide open windows or on a sleeping porch. 4. You should eat and drink nothing that irritates the nervous system, like tea, coffee, or alcohol. Of course you should not use tobacco in any form. 5. You should eat little meat. If you are fond of meat, take a small portion of beef, mutton or breast of chicken or fresh fish once or twice a week or at most three times a week. 6. You should drink a great deal of milk and eat foods that are prepared with milk, such as milk soup, milk toast, etc.; cream and buttermilk are also especially advisable. 7. You should avoid beef soup, beef tea, or any kind of meat broths. 8. You should eat an abundance of cooked fruits and cooked vegetables, or ripe raw fruits, or drink fruit juices prepared from ripe fruits. 9. You may eat eggs, bread, butter, toast, rice, cereals. 10. You should drink an abundance of good water, or if this is not available, you should boil the drinking water for twenty minutes, or drink distilled water.

Gastric Ulcer.—Willard J. Stone (*Journal A. M. A.*, Sept. 30, 1916) brings forth considerable evidence and strong arguments to show that gastric hyperacidity, with or without ulcer, is promoted by an excess of carbohydrate in the dietary, as well as by other contributing factors. Among the contributing factors, which should always be remedied by appropriate measures, are gastroptosis, visceroptosis, oral sepsis, gallbladder disease, chronic appendicitis, etc. Following the relief of any of such provocative conditions the treatment of ulcer or of hyperacidity should be mainly dietetic, and this demands, above all, a sharp restriction in the intake of carbohydrate and the use of frequent small feedings. Such carbohydrate restriction should exclude all foods which contain over ten to fifteen per cent. of carbohydrate. The foods which may be taken by such patients are comprised in the following lists: Eggs, soft boiled, poached, or in omelette; fish, bacon, chicken, oysters or clams in broth, custard with small amount only of sugar, buttermilk, cream, cheese, olive oil, and tea. These are essentially the proteins and fats. The carbohydrate containing foods may be grouped according to their content into: Those with five per cent. of carbohydrate, which are asparagus, watercress, cauliflower, spinach, eggplant, lettuce, dandelion or beet greens, string beans, olives, and the pulp of grapefruit. Those containing ten per cent. of carbohydrate are boiled onions, squash, turnips, carrots and beets, lemon juice, orange juice and pulp, peaches, watermelon, canteloupe, and hickory nuts or filberts. The fifteen per cent. group includes green peas, parsnips, canned lima beans, the pulp of baked apple, pears, pecans, almonds, and English walnuts. In addition to articles from these lists the patient may be allowed

one potato, three slices of toast, one portion of cereal or rice, and puree of peas, corn, or spinach. Supplementing the restriction in carbohydrates there should also be restriction of condiments, pickles, vinegar, coffee, and chocolate. Between meals and at bedtime a glass of milk should be taken and after both the milk and the meals the patient should take half to one teaspoonful of the following powder in a third of a glass of water:

℞ Magnesii oxidi ponderosi, } .....āā 5.0;
Bismuthi subcarbonatis, . }
Sodii bicarbonatis, ...20.0.
M. Fiat pulvis.

Where there is also hypersecretion this powder should be given every two hours without respect to meals. If it is desired to prevent the formation of curds in the stomach, we may add 0.2 gram of neutral sodium citrate to each thirty mils of milk. If there is persistence of organic acid formation the stomach may be lavaged once daily with a one in 1,000 solution of salicylic acid. Under these restrictions, with an adjustment of the periods and amounts for individual feedings to suit the particular case, the vast majority of cases of hyperacidity and of gastric ulcer will be cured, and in the past five years the author has had to have gastroenterostomy performed only twice.

British Beef Stew.—The famous Russian General Brusiloff and a distinguished British novelist have agreed on the estimate that the war will continue until some time next summer or autumn, but it is reported in the United States that the British Government has recently contracted for 600 million cans of beef stew. Allowing each man a can a day, the *British Medical Journal* for September 30, 1916, calculates that this would supply an army of three million men for a period of nearly two years; but perhaps the men of the British army are capable, on the average, of consuming two cans of beef stew daily. Dr. John Aulde, of Philadelphia, has published an analysis of this beef stew. He says that it is composed of cooked beef six ounces, rice four ounces, beans one ounce, onions one ounce, carrots one ounce, and that its value in food utilized is protein fifty grams, fat sixty grams, carbohydrate thirty-seven grams, yielding 914 calories. He compares this with the balanced ration well understood by American stockmen. This contains fifty grams protein, fifty grams fat, 200 carbohydrate, and yields 1,490 calories. The carbohydrate in a day's diet should be as it is in this ration—four times the protein and the fat one fifth of the whole. The British army stew is, of course, amplified by bread, jam, etc., and there is no advantage in putting more vegetable into it than will go to make a palatable stew. We must say the formula sounds an appetizing one, and ought to be much more acceptable than bully beef to all excepting those few unfortunate individuals who cannot bear onions. Doctor Aulde draws attention to the importance of an adequate supply of calcium in the diet. The beef stew contains 1.5 grain of calcium oxide and the same amount of magnesium oxide. The average dietary of American homes contains ten and a half to fifteen grains of calcium, and about half the quantity of magnesium; and he asserts that "when these proportions are reversed susceptibility to illness follows." "Deficiency of calcium," he says, "is the pivot in the production of rickets, a deciding factor in creating susceptibility to tuberculous infection in both adults and children, and a demonstrable condition in Bright's disease and diabetes. Recent investigations by the United States Public Health Service prove beyond question that the loss of lime salts is the sole cause of pellagra." This is a rather alarming picture, but even those who feel difficulty in accepting it as true will be pleased to know that our soldiers are not to be exposed to the risks enumerated.

Food in Shanghai.—As the preventable diseases specially prevalent in Shanghai are mostly caused by infected food, food inspection has been considered of paramount importance. The foreign food supply is under complete sanitary supervision, and the same is gradually being done for the Chinese, premises being licensed as soon as the necessary conditions have been met. The periodical analyses of water supply by the Shanghai Waterworks Company show that filtration is carefully done. The question of the prohibition of water closets is one that chiefly concerns the purity of the water supply, and is therefore of fundamental importance to the community.

There has been a progressive improvement in the quality of milk supplied, continue the Colonial Medical Reports of the Shanghai Health Department, in the *Journal of Tropical Medicine and Hygiene* for September 1, 1916. The standard of cleanliness in dairies has been maintained. The windows of the milk rooms are now required to be unopenable and provided with perforated zinc instead of glass, and the door with a spring slam to prevent ingress of flies. Efforts are being made to prevent the smuggling of milk from unlicensed dairies in Pootung. As regards the result of punishment, fining is the least effective, the offense being invariably repeated, while it tends to increase the price of milk to compensate for losses sustained. On the other hand, imprisonment and the cangue have a decidedly deterrent effect.

The licensed butchers, poultry, game, and vegetable shops have been kept in good sanitary condition. The regulation of fruit shops has presented great difficulty. Endeavor has been made to get the dealers to keep their skinned fruits in flyproof cases, but with indifferent success. It is considered best to rely on the public, both foreign and Chinese, to sterilize fruit, as it is impossible to insure that fruit is not exposed to inspection by flies at some stage of its journey from the tree to the consumer.

Residents are requested not to patronize hawkers of fruit and other foodstuffs who come to their houses. The examination of cattle and carcases at the municipal slaughter house affords adequate protection of the meat supply. Good meat is stamped with a circular stamp for beef and a triangular stamp for mutton, pork, and veal, with the words "killed municipal slaughter house" and the date of slaughter. Meat inferior in quality, but free from disease, passed for sale on stalls only, is marked "second quality."

Editorial Notes and Comments

NEW YORK MEDICAL JOURNAL
INCORPORATING THE
Philadelphia Medical Journal
and The Medical News.
A Weekly Review of Medicine.

NEW YORK, SATURDAY, OCTOBER 28, 1916.

IS THE PASTEURIZATION OF MILK ADVISABLE?

The pasteurization of milk is a method, regarding the merits of which there is considerable disagreement; it is a much vexed question. On the one hand, it is argued that by pasteurization certain elements of the milk essential to proper nutrition. the vitamines, are destroyed or impaired, and that the value of the milk thus treated as a food for infants is greatly depreciated. Infantile scurvy is said to be caused in many instances by pasteurized milk and if lack of vitamines is largely responsible for infantile scurvy and if pasteurization destroys or impairs the vitamines, the argument is certainly forcible and to some extent convincing. Many authorities have been much impressed by these views, and some even have been converted.

If it is granted, however, that a pasteurized milk is not so nourishing as it should be, that is, is lacking in elements which appear to be necessary to good health, still the method possesses several counterbalancing advantages. When it is not scientifically and carefully done, the method is obviously worse than useless, for it engenders false confidence, and therefore, instead of protecting against disease, it is likely to spread infection. When the method is carried out on sound scientific principles, however, according to the views of a large number of medical men who have investigated the matter clinically and otherwise, it does provide at least fairly adequate protection against infection. Recently, it has been stated that the virus of acute poliomyelitis is conveyed by the agency of food, and especially in the case of infants, by the agency of milk. If the statement is substantiated then there can be little doubt that boiling or pasteurizing milk will go far toward checking an epidemic of infantile paralysis. In fact, it has also been asserted that no infants who had been fed on pasteurized milk from the public milk stations were attacked by poliomyelitis. If this is the case, it provides remarkably strong evidence in support of pasteurization, but further investigations of a most searching character must be undertaken before such a statement can be accepted. Undoubtedly pasteurization of milk is a protective measure of value when properly carried out, and it is probable that some of the prejudice against the method is due to its careless performance. Whether its advantages counterbalance its drawbacks has not been proved, consequently we must still keep an open mind on the subject.

THE CONTAMINATION OF MILK.

On account of the necessity of milk as a food it is probably the one substance that has been investigated thoroughly from all aspects; it is a most excellent medium for the multiplication of bacteria and its chemical composition can be altered by heating.

If there were no changes from exposure to heat, rendering milk safe for food would be comparatively easy. Unfortunately a temperature that destroys bacteria will have a bad effect on the medium itself. In order to have the best results it is necessary that the milk shall from the first be as free as possible from bacteria. If this milk is then pasteurized the consumer will be protected; many precautions, however, must be taken. Cleanliness is the essential feature, not only of the man and his utensils, but of the cow as well; care is thereby entailed and that means additional expense. The more the quality of the product is improved, the greater becomes the cost, and this falls most heavily on the poorer classes, those least able to pay.

To keep down the cost of production has been the desire of the dairyman, but when he is paying

high wages and when his own cost of living is going up he must charge more. In order to obtain the milk more economically various mechanical devices are employed; a common one is the milking machine. The manufacturers of these appliances give full directions how to keep them clean; but as they consist mainly of rubber tubing there are many difficulties with which to contend.

Ruediger (*Journal of Infectious Diseases,* October, 1916) has recently made comparisons between the bacterial counts of milk drawn by hand, by unsterilized milking machines, and by machines thoroughly scalded. In one dairy the bacteria count when the milk was drawn by hand into a sterile bottle was 860; with the milking machine as generally used the count was 2,450,000; but when all parts of the machine and can were thoroughly scalded the count dropped to 2,430. As the author states it: "When we consider the fact that this milk is drawn through rubber tubes about three feet long and which have several connecting joints, and that these were cleansed but once a week, we are not greatly surprised by the result. The filthiness of the connecting joints and of the interior of the tubes in hot weather can easily be imagined."

If there is to be control over the quality of the milk, it is evident, as Ruediger points out, that the only way is by bacteriological counts. In no other way can the cleanliness of the milk be determined so accurately.

A NEW ELECTRIC PROBE.

We may not believe with some that electricity will in time solve all our mechanical problems, but the present war is demonstrating its effectiveness in many ways; for example, the repulse of armed forces by electricity with charged wire fences, rapid communication by portable telephones, lighting of the trenches, electrotherapy for paralyzed limbs, etc. Now this powerful agent bids fair to be useful in another way, that is, in the troublesome problem of discovering the whereabouts of a bullet hidden in the tissues. Many telephone probes and magnetic deflectors have been devised, but the chief objection to all of them is the grave one of impracticability.

A new probe which makes use of electricity is worked according to the following plan: A galvanometer is used to which are attached a fine metal probe and a contact wire. The latter is placed in the edge of the wound in contact with the tissues, while the probe is employed in the usual manner. There being no difference in potential between the wire and the probe the galvanometer is undisturbed until the probe comes in contact with a bullet, when a voltaic cell is formed, the foreign body being one pole, the contact wire the other, while the blood serves as the electrolyte. A marked deflection of the galvanometer then occurs.

The apparatus is comparatively cheap, costing about fifty dollars, is portable, and has been found quite trustworthy in the several military hospitals where it has been tested. If these reports of its value are well founded, it will no doubt replace the telephone probe to which most surgeons object on the ground that they cannot distinguish the sound of the probe striking a foreign body from other sounds heard constantly in the receiver.

FOOD VALUES IN BREAD.

Since realizing the part played by food elements in metabolism, in diseases, and in the treatment of certain pathological conditions, a great deal of painstaking scientific investigation has been undertaken. The results thus far achieved have been more than gratifying, and of much constructive value. The food factor in diabetes is, perhaps, the longest known, that of pellagra and beriberi of more recent origin, and the factor in the retention of the general health by proper diet, is now taking first place, not alone from the standpoint of a carbohydrate protein balance, but from the standpoint of the retention of all natural food elements unaffected by outside agencies. The observation that monotonous dietaries, even when large in quantity, such as are consumed among certain of the poor, are not satisfying to the organism, with resulting debility of various kinds and degrees, and that a mixed diet, even if small in quantity, is more ideal, is now altogether beyond dispute.

The organism requires for orderly metabolism that all foods be allowed to contribute their share of a necessary food element known as vitamine. Some foods naturally contain small quantities, and the deficiency must be supplied by mixed dietaries together containing sufficient quantities. Moreover, the vitamine in the food elements must not be destroyed or attenuated by mechanical, chemical, or other processes.

Economic necessities in the manufacture of food products are responsible for the destruction or separation of the nutrient vitamine-containing part from the part actually used as food. This treatment has been particularly administered to bread stuffs. Modern rolling mill processes separate the endosperm or starchy part from the sperm and the bran. The latter contains most of the fat, protein, ash, and vitamine, but is discarded as food. The highly milled product is particularly deficient in vitamines.

Recent experiments carried on by the Public Health Service as explained in the *Reports,* showed that fowls live indefinitely on the old fashioned product, but die within a short time from polyneuritis when fed exclusively on the highly milled products. High milling in its mechanical as well as in its physiological effect is akin to polishing of rice, which causes the polyneuritic condition known as beriberi. Pellagra, on the other hand, is caused by feeding cereal products naturally deficient in vitamines.

The vitamine content of food may be determined from the presence of phosphorus pentoxide obtained by drying and ashing, distributed like, though not contained in the vitamine molecule. To be wholesome, rice must contain not less than 0.4 per cent. of phosphorus, corn products not less than 0.5 per cent., and wheat flour not less than one per cent. Less than these percentages implies a significantly deficient vitamine content.

Moreover, the vitamine content is reduced or destroyed by the introduction of baking soda into the highly milled or even into the old fashioned product, in order to make it lighter. The alkalies are especially destructive of vitamine when exposed to high temperatures. Fowls die on the addition of soda; but a fatal termination is prevented by the addition of vitamine obtained from other foods. Sufficiently soured milk or tartaric acid combined with the baking soda mixture neutralizes the vitamine destructive power of the alkali. Similarly, the introduction of soda into cooking is a pernicious practice. The alkali shortens the time required for cooking, but destroys the vitamine.

The metabolic disturbances caused by vitamine deficiency, therefore, can in large part be overcome by lower milling processes, by ceasing the use of unneutralized baking soda mixtures, and by the consumption of high value vitamine foods, such as fresh eggs, milk, and meat.

THE PREVIOUSLY INSANE RECRUIT.

One of the most puzzling problems with which the recruiting surgeon has to deal is the determination of the mental status of the candidate for enlistment. Many who are high grade imbeciles, who have previously had a psychosis, or who are potential psychopaths, show very little to the observer, even to the medical man if he is unskilled in psychiatry. Consequently in the ordinary enlistment of men in the United States service which goes on in times of peace, many men are accepted who later manifest psychoses and cause the government much trouble and expense before final disposal is made of them. Should war occur we must expect the occurrence of conditions such as have been observed in all the countries now at war, that is, a rush of volunteers, anxiety on the part of the recruiting officers to swell the ranks at the front as quickly as possible, overwork of the military surgeon, and the natural result, the passing of men who are unfit for duty, physically or mentally.

It is the latter class who are most apt to be accepted to the subsequent detriment of the service. Many cases, for example, have come to the attention of the military authorities in Great Britain. Sir George Savage read a paper dealing with these cases before the annual meeting in July of the Medico-psychological Association of Great Britain and Ireland. He had found that many military surgeons, in their natural desire to help their country and holding the enlightened view that one attack of mental disorder should not be held against a man who had made an apparently complete recovery, had accepted men with such a history, only to have them break down, in training or immediately after arriving at the front. A more careful investigation of the family history then usually revealed that there was bad heredity in addition to previous mental disorder.

The attitude of the friends and relatives of the candidate often seemed to be responsible for the enlistment of such men; they were urged to enlist by employers and others who thought they were cowardly because they hesitated, the real reason being fear of their own condition. Finally, unable to bear the stigma of cowardice, they enlist, tell the surgeon they had a mental breakdown years ago, but are all right now, are accepted, and soon collapse under the emotional stress of warfare.

The consensus of the British experts now seems to be that no such recruit should be enlisted; and this is wise. We should not think of advising a man who had had one attack of tuberculosis to accept a job in a dusty workshop; we should not encourage a man who has had a mental breakdown to put himself in a position where he will be subjected to mental strain. The environment of such persons should be as little exacting and as free from emotional tension as possible, yet the exact opposite prevails in an army engaged in sanguinary conflict. These soldiers will cost any government more trouble attending to the many who break down than the few who escape unscathed are worth to it; and our own country should formulate some method of weeding out these men before the exigencies of war make the problem doubly dangerous. It is impossible to foresee how many of our recruits would break down under the strain of modern warfare, but judging from the increase of insane and nervous invalids in this country the number would be large. This is a phase of preparedness that should be heeded.

DISEASE AND WORKMEN'S COMPENSATION.

An employee who suffers from lead poisoning is not entitled to compensation under the Connecticut law, according to *Public Health Reports* for October 6, 1916. The Supreme Court of Errors of Connecticut has decided that the Connecticut workmen's compensation law does not provide for payments to an employee from an occupational disease.

An employee of the American Steel and Wire Company was incapacitated for a short time by lead poisoning contracted in the course of his employment. The court decided that he was not entitled to compensation.

The opinions of Mr. Justice Beach, in delivering the decision of the court, and of Mr. Justice Wheeler, dissenting, are interesting discussions of the question presented to the court. They are published on pages 2797 to 2810 of the same issue of *Public Health Reports.*

Obituary

D. BRADEN KYLE, A. M., M. D.,

of Philadelphia.

Doctor Kyle died at his residence, 1517 Walnut Street, Philadelphia, on October 23d. He was born in Cadiz, Ohio, in 1863, and graduated from Jefferson Medical College in 1891; subsequently he received an honorary Master in Arts from Dickinson College, Pa. After graduating at Jefferson, Doctor Kyle served as assistant demonstrator in pathology, a subject of which he eventually assumed the chair. In 1896 he became professor of laryngology, and was also consulting laryngologist to St. Agnes Hospital, bacteriologist to the Philadelphia Orthopedic Hospital, and in 1910 and 1911 president of the American Laryngological Association. Doctor Kyle was known throughout the country by his *Textbook of Diseases of the Nose and Throat;* he was at one time a frequent contributor to the NEW YORK MEDICAL JOURNAL. His widow survives him.

News Items

Change of Address.—Dr. Andrew J. Love, to 521 West 142d Street, New York.

Southern Medical Association.—The annual meeting of this association will be held in Atlanta, Ga., November 11th to 16th, under the presidency of Dr. Robert Wilson, Jr., of Charleston, S. C.

Pediatrists to Meet in Boston.—On Saturday, November 4th, the Philadelphia Pediatric Society and the Section in Pediatrics of the New York Academy of Medicine will be the guests of the New England Pediatric Society in Boston.

The American Society for the Control of Cancer, organized in 1913, in its first report to the Congress of American Physicians and Surgeons, outlines the scope of its work in conducting an educational propaganda for the prevention and cure of cancer. The society is distributing its circulars to medical societies and public health agencies throughout the country. It is also acting as a clearing house for the collection of statistical data from national mortality and operative reports. The central office is situated at 25 West Forty-fifth Street.

Meetings of Medical Societies to Be Held in Philadelphia during the Coming Week.—Tuesday, October 31st, Medicolegal Society; Wednesday, November 1st, Physicians' Motor Club (directors), College of Physicians; Thursday, November 2d, Obstetrical Society, Southeast Branch of the County Medical Society; Friday, November 3d, Kensington Branch of the County Medical Society.

Canadian Committee on Orthopedics.—The Military Hospitals Commission of Canada has appointed a committee, with the following members, to consider the matter of artificial limbs for soldiers: Dr. Clarence L. Starr, of Toronto, Dr. William E. Gallie, of Toronto, Dr. A. MacKenzie Forbes, of Montreal, Dr. Francis J. Shepherd, of Montreal, and Dr. Frederick E. Thompson, medical superintendent of the commission.

Defective Teeth Among Rural School Children.—A recent investigation made by the United States Public Health Service in connection with studies of rural school children showed that 49.3 per cent. of the children examined had defective teeth, 21.1 per cent. had two or more teeth missing, and only 16.9 per cent. had had dental attention. Over 14 per cent. never used a tooth brush, 58.2 per cent. used one occasionally, and only 27.4 per cent. used one daily.

State Medical Society of Delaware.—The annual meeting of this society was held in Milford, Tuesday, October 10th, under the presidency of Dr. George I. McKelvey, of Dover. Officers for the ensuing year were elected as follows: President, Dr. James Beebe, of Lewes; vice-president, Dr. John Ball, of Elsmere; secretary, Dr. G. W. K. Forest, of Wilmington; treasurer, Dr. Samuel P. Rumford, of Wilmington. Next year's meeting will be held in Middletown.

Mississippi Valley Medical Association.—At the forty-second annual meeting of this association, held in Indianapolis, October 10th, 11th, and 12th, the following officers were elected: President, Dr. Channing W. Barrett, of Chicago; first vice-president, Dr. Francis M. Pottenger, of Monrovia, Cal.; second vice-president, Dr. Frank B. Wynn, of Indianapolis; secretary, Dr. Henry Enos Tuley, of Louisville (reelected); treasurer, Dr. S. C. Stanton, of Chicago (reelected). Next year's meeting will be held in Toledo, Ohio.

Texas Medical News Changes Its Name.—Dr. M. M. Smith, editor and publisher of the *Texas Medical News,* announces that with the October issue this periodical will be merged into a new, national publication which will be known as *Medical Insurance and Health Conservation.* The subscription price of the new periodical will be two dollars a year, and Doctor Smith will continue as managing editor, with headquarters at Dallas, Texas. It is said that this is the first periodical devoted exclusively to medical insurance and health conservation topics.

Medical Association of the Southwest.—Dr. E. S. Lain, of Oklahoma City, Okla., was elected president of this society, at the eleventh annual meeting, held in Fort Smith, Ark., October 2d, 3d, and 4th, and other officers were elected as follows: Dr. Howard L. Snyder, of Winfield, Kansas, first vice-president; Dr. John H. Thompson, of Kansas City, Mo., second vice-president; Dr. Matthew M. Smith, of Dallas, Texas, third vice-president; Dr. Charles S. Holt, of Fort Smith, Ark., fourth vice-president; Dr. Frederick H. Clark, of El Reno, Okla., secretary-treasurer. Next year's meeting will be held in Kansas City.

The National Committee for the Prevention of Blindness will hold its second annual meeting in the New York Academy of Medicine on the afternoon of November 24th, at 4:30 o'clock. President William Fellowes Morgan will preside, and it is expected that some of the honorary officers will be present. The principal address will be delivered by Dr. John McMullen, surgeon, United States Public Health Service, whose eminent services in the work of stamping out trachoma in the Appalachian Mountains have become a matter of nationwide interest. Doctor McMullen will use his lantern slides and describe the campaign which has been conducted under his immediate supervision.

German Death Rate.—Mortality in Germany, after reaching the low record of 14 per mille in 1913, has followed a steadily ascending curve during the war. The figures for 1914 were 16.1 per mille, in 1914 there was an increase to 19.7, and the record for the first seven months of 1916 is 16. These statistics include civilians and soldiers. Infant mortality, however, continues to follow a descending curve. The number of deaths per centum new births, after showing a slight increase from 14.1 in 1912 and 1913, to 15.6 in 1914, dropped to 14.5 in the first year of the war. For the last year the percentage has been 12.9.

Vermont State Medical Society.—The 103d annual meeting of this society was held in St. Johnsbury, Thursday and Friday, October 12th and 13th, under the presidency of Dr. Edward H. Ross, of St. Johnsbury. Officers to serve for the ensuing year were elected as follows: President, Dr. Clarence H. Beecher, of Burlington; vice-president, Dr. Charles W. Howard, of Shoreham; secretary, Dr. William G. Ricker, of St. Johnsbury; treasurer, Dr. Edward H. Martin, of Middlebury; executive committee, Dr. Orlando G. Stickney, of Barre, and Dr. Chester S. Leach, of Hyde Park. Dr. Frederick W. Sears, of Burlington, was elected chairman of the legislative committee. Next year's meeting will be held in Barre.

Increased Appropriation for Health Work in Schools.—The 1917 budget estimate of the Bureau of Child Hygiene of the Health Department of the City of New York calls for $75,240 more than last year for school health work. The additional money is needed for enlarging the staff of medical inspectors and nurses, adding 25 medical inspectors and 52 nurses. At present there are 100 inspectors and 200 school nurses. It is also proposed to add six dental hygienists to the staff for prophylactic work. The 1915 reports on medical inspection show that health conditions among school children are too serious to be neglected. About one third of the pupils enrolled in the public and parochial schools of the city were examined during the year for physical defects, and of these 72.6 per cent. were found to have physical defects which required treatment, as follows: Defective vision, 14.5 per cent.; defective nasal breathing, 9.5 per cent.; hypertrophied tonsils, 11.2 per cent.; defective nutrition, 5.3 per cent.; defective teeth, 63.9 per cent.; and to a lesser extent there were cases of cardiac and pulmonary disease, defective hearing, and orthopedic defects. The great number of children to be examined and the small staff of physicians available made it impossible at times to give each child a complete physical examination, with the result that 42.2 per cent. of the children did not have the vision tested.

Civil Service Positions.—Among the positions for which the Civil Service Commission of the State of New York will hold examinations on December 2d, are the following:

Woman physician (regular or homeopathic), State hospitals and institutions. $1,000 to $1,500 and maintenance. Candidates must be licensed medical practitioners of the State of New York, and must have had at least one year's experience on the medical staff of a hospital or three years' experience in the general practice of medicine.

Physician, State prisons and reformatories. Salary $2,000 without maintenance. Examination open only to men who are licensed medical practitioners in this State, who are not less than twenty-five years of age, and who have had at least three years' practice.

Deputy medical examiner, Bureau of Deportation, State Hospital Commission. $3,500. Applicants must be physicians licensed to practise in New York State, and with not less than five years' experience in the practice of medicine. Minimum age limit thirty years. Applicants will be expected to have a knowledge of the insanity law, and experience in the care and treatment of the committed or alleged insane in the New York State hospitals or elsewhere, or knowledge and experience of the problem of the alien insane, and their deportation.

For further information regarding these examinations address the Civil Service Commission, Albany, N. Y.

New Red Cross Bureau in New York.—To facilitate the dissemination among Red Cross chapters of information about the needs of European war sufferers, the American Red Cross has established a special information bureau in the Metropolitan Tower, New York, under the charge of Mr. Albert W. Staub, superintendent of the Red Cross receiving and shipping station at the Bush Terminal, Brooklyn. Mr. Staub will fill the two offices. His experience during the past two years as head of the receiving and shipping station and the steady correspondence which his office has with the receiving and forwarding representatives of various recognized relief agencies in Europe will enable him to keep the more than 200 Red Cross chapters in this country constantly advised as to the needs of the foreign Red Cross societies and representatives.

The Navy a Field for Medical Work.—The surgeon general of the United States Navy has issued a number of circulars of information for persons desiring to enter the medical corps, and directs attention to the fact that the navy offers a special field for medical work. Legislation has recently been enacted which will provide for approximately 300 additional medical officers in the Medical Corps of the United States Navy. The pay ranges from $2,000 a year, with quarters or an allowance therefor, for assistant surgeons with the rank of lieutenant, junior grade, to $8,000 with allowance upon attaining the grade of medical director with the rank of rear admiral of the upper half. Applicants must be between the ages of twenty-one and thirty-two years, citizens of the United States, and must submit satisfactory evidence of preliminary and medical education. These circulars may be obtained by addressing the Surgeon General, United States Navy, Navy Department, Washington, D. C.

New Officers of County Medical Societies.—At the annual meeting of the Ontario County Medical Society, held at the Oakmount Sanatorium, East Bloomfield, N. Y., on Tuesday, October 10th, the following officers were elected: Dr. Charles W. Selover, of Stanley, president; Dr. Malcolm S. Woodbury, of Clifton Springs, vice-president; Dr. Daniel A. Eiseline, of Shortsville, secretary-treasurer; censors, Dr. O. J. Hallenbeck, of Canandaigua, Dr. J. J. Collie, of Geneva, and Dr. Joseph A. Saunders, of Clifton Springs.

Dr. George F. Rogan, of Medina, was elected president of the Orleans County Medical Society, at the annual meeting held in Medina, Thursday, October 12th, and other officers were elected as follows: Dr. R. E. Brodie, of Albion, vice-president; Dr. F. W. Scott, of Medina, secretary and treasurer; censors, Dr. Edward L. Munson, of Medina, Dr. L. G. Ogden, of Barre, and Dr. C. E. Padelford, of Holley.

Personal.—Dr. Arthur R. Edwards has resigned as dean of the Northwestern University Medical School, Chicago, and Dr. Arthur I. Kendall, professor of bacteriology in the institution, has been made acting dean.

Dr. W. Wayne Babcock, of Philadelphia, gave a talk on his experiences in Alaska, Yukon, and British Columbia, at a meeting of the Physicians' Motor Club, held in Philadelphia on Tuesday evening, October 24th. The address was illustrated with stereopticon views.

Dr. Nathan Finklestein, of Pittsfield, Mass., has been appointed instructor in urology and cystoscopy at the New York Post-Graduate School and Hospital and will begin his new duties on November 1st.

Dr. John T. Bottomly, of Boston, was elected president of the St. Luke's Guild of Catholic Physicians, at the annual meeting held at the Carney Hospital, Wednesday, October 18th. Dr. John R. Slattery was elected vice-president of the guild, and Dr. John J. Sullivan, secretary-treasurer.

Dr. Fernando Calderon, a Filipino, has been appointed director of the Government Hospital at Manila, to succeed Dr. William E. Musgrave, who resigned recently.

Dr. Walter H. Brown, of Boston, has resigned as State epidemiologist, to take up work in Bridgeport, Conn., where he will act as executive officer of the Board of Health. His resignation from the Massachusetts State Department of Health takes effect on November 1st.

Modern Treatment and Preventive Medicine

A Compendium of Therapeutics and Prophylaxis, Original and Adapted

THE THERAPEUTICS OF A PHARMACOLOGIST.

By A. D. Bush, M. D.,

Professor of Pharmacology and Therapeutics, University of Southern California.

Forty-second Communication.

VALVULAR DISEASE

(Concluded.)

An exceedingly important matter to keep in mind concerning administration of digitalis in heart affections is its long continued action. In a series of observations conducted with normal human subjects in my laboratory it was found that a single dose of digitalis (m. xx of the tincture, orally) produced a rise in blood pressure continuing for over two days, these results confirming earlier observations by Marvin and myself. Imagine what might have been the cumulative action had that dose been several times repeated during the day! It is essential that great deliberation be exercised in bringing the heart under the full influence of digitalis. There is rarely adequate reason for hurrying this process, and undue haste will easily precipitate an uncomfortable if not alarming case of poisoning. Furthermore, when once digitalis control is sufficiently secured, scrupulous caution must be exercised that the absolute daily minimum be not exceeded. Better have your patient experience a slight recurrence of earlier symptoms than to have toxic ones superimposed.

Concerning other drugs which have been recommended, a few words may be said. In the latest edition of his textbook on medicine Anders says: "Strychnine given hypodermically in full dose, grain 1/30 to grain 1/15, is the most efficient cardiac stimulant known to medical science," and recommends its use in "sudden failure of heart power." In my laboratory, repeated tests of groups of men with strychnine in one twentieth grain doses, administered both intramuscularly and orally, have failed to show any stimulant action on the heart at all. On the contrary, there was a slight tendency toward a slowing of the heart rate, due in part to an indefinite stimulation of the inhibitory centre and in part to moderately elevated blood pressure: the rise in blood pressure may be ascribed in small part to centric vasomotor stimulation and in larger part to heightened spinal irritability with reflex influence on the muscle system. Several other investigators have arrived at the same findings, so it is difficult to perceive any physiological basis for Anders's statement. In fact, it would rather seem that the physician who places reliance on strychnine in "sudden failure of heart power" is leaning on a broken reed. To be sure, strychnine is decidedly valuable as a spinal stimulant, and as such may well be advantageously employed, but it should be used with full recognition of the real pharmacological seat of its activity.

Caffeine has been recommended as a heart stimulant, and very often it works well in assisting to normalize a functionally deranged mechanism, but it is of little or no benefit in organic disabilities except as a diuretic accessory.

Nitroglycerin is beneficial in cases where an unduly high arterial tension makes too arduous the work thrown upon the left ventricle. Coincidentally nitroglycerin tends to produce a depression of both the cardiac muscle and the cardioinhibitory centre—facts which should be kept in mind when considering the indications for the drug. Where its constant use seems to be demanded, the dose should be slowly increased to compensate for the growing tolerance which the system usually manifests for this drug.

Though the advice is trite, it seems wise to add that in the presence of any systemic disability like syphilis, appropriate treatment should be vigorously but cautiously administered. The clinical pathologist uncovers many a case that is in need of an adequate combination treatment of mercury and potassium iodide. There cannot be too frequent iteration of this reminder.

New Method of Drainage in Traumatic Suppurative Arthritis of the Shoulder and Elbow Joints.—H. Chaput (*Paris médical*, August 12, 1916), in comminuted fracture of the upper end of the humerus complicated with suppurative arthritis, advises removal of the head of the humerus for the purpose of securing better drainage. The head should be conserved only if it is intact, eroded, or merely perforated; and in the latter instance filiform drainage of the perforation must be established. To secure complete drainage of the shoulder, Chaput makes a long anterior incision over the axis of the humeral head, incises the whole of the serous sheath surrounding the long tendon of the biceps, and cuts the capsule completely at its insertion on the humerus and dislocates the head upward, as though to remove the latter. Strands of silkworm gut are then passed in the form of loops through all abscess diverticula. Another is passed anteroposteriorly just below the lower margin of the humeral head, emerging posteriorly a little below the acromion; another, above the external portion of the anatomical neck, with posterior counteropening, and preferably still another, within the surgical neck, emerging posteriorly in the axilla behind the vessels and anteriorly through the main incision. The latter is closed with interrupted sutures, spaces being left for emergence of the filiform drains. In traumatic conditions at the elbow, to obtain prompt drainage, Chaput makes a short incision on either side of the olecranon, enters the joint, and passes a filiform drain beneath the triceps tendon. Another, posterior, incision is then made, at the level of the neck of the radius, the extension of the joint at this point opened, a blunt

needle introduced from behind forward within the neck, the anterior muscles are perforated, the skin is lifted up anteriorly and incised, and an anteroposterior filiform drain inserted, to be tied in a loop on the outer aspect of the limb. Complete elbow drainage is indicated when the rapid drainage fails, provided the bony constituents of the joint are not fractured. The long median incision for resection of the elbow is made, the humerus, ulna, and radius are freely denuded, and the humerus is dislocated as though for excision. The various circumhumeral abscesses present are thus exposed. The ulna and radius are denuded to a point below the coronoid process. To dram the joint freely, a double transverse silkworm gut drain is passed anterior to the olecranon and its extremities caused to emerge through small posterolateral openings. The olecranon fossa of the humerus is then pierced and two anteroposterior strands passed through it, both anterior extremities of which are carried backward, one internally, the other without the radial neck, and loosely tied behind with the posterior extremities. Finally a cord of soft rubber is passed transversely in front of the humerus and above the articular eminence, its ends emerging through lateral openings. Another is passed in front of the radius and ulna, below the coronoid, its ends likewise emerging laterally. The wound is left open and exposed to electric light daily. In the event of failure of this treatment, excision or amputation are the procedures of last resort.

Rapid Cure of Fistula in ano without Fecal Incontinence.—Chaput (*Paris médical*, August 26, 1916) sets forth the advantages of filiform drainage in fistula in ano. In blind external fistulas, he first lays open the fistula, explores it with a grooved director to locate its branches and diverticula, and carefully curettes all its recesses. Curved forceps are then introduced to the bottom of the tract and pushed from behind forward through the soft tissues until beneath the skin, carefully avoiding perforation of the rectum. An incision is made over the forceps, the latter pushed out through it, and a piece of silkworm gut caught with it, drawn back, and knotted to form a loop. The same maneuvre is then repeated, but from before backward, and another loop made. Each diverticulum found is similarly treated, but with a single loop only. The skin incisions are then carefully sutured, merely allowing the loops to pass, and a dressing of zinc peroxide and aseptic gauze is applied. No attempt is made to induce constipation, a liquid diet, however, being ordered, and the patient allowed to go to stool whenever he desires. After each act of defecation the area is cleansed with spirit of camphor, methylene blue applied to the loops, and a fresh dressing provided. After fifteen to twenty days the oozing is reduced to practically nothing. The loops are now removed, but rest and dressings are continued until healing is complete, usually ten or fifteen days later. A blind internal fistula is turned by incision into a complete fistula and treated like the latter. The same preliminary treatment is applied as in blind external fistula and, in addition, the exact site of the opening in the rectum ascertained with the finger in the latter. The margins of the rectal orifice are then fixed with four Kocher forceps and the entire circumference of the mucous opening is resected; this may be done through either the rectum or the perineum. A piece of silkworm gut is next passed as a loop through the mucous orifice and the anus, on the one hand, and the skin incision, on the other. Perineal incisions are sewn up with sutures far apart, to permit of fecal evacuations. Diverticula are dealt with as already described. A dry dressing is applied, the patient put upon a milk diet, and constipation for a week produced with extract of opium. The patient is then allowed to defecate, the dressing being renewed after each act. He must not walk. Constipation is induced for weekly periods, with intervals of two or three days, until the close of the treatment. The loops are removed when oozing has nearly ceased; rest in bed and dry dressings are continued up to complete healing. Horseshoe fistulas and fistulas with multiple tracts are first freely incised on the skin side, without entering the rectum; each diverticulum is explored with the grooved director and catheterized with curved forceps which is passed out through a skin incision and used to carry back a loop, to be knotted on the outside.

Climate in the Treatment of Tuberculosis.—G. B. Fish (*Medical Record*, September 30, 1916) believes that climate generates the nerve force needed by the tuberculous patient to conform to the unaccustomed restraint and the rigid mode of living. Change of climate exerts a cheering and salutary effect on the patient's mind, and this mental element should be given serious consideration. There is no one best climate for tuberculosis and many things must be considered in advising a change, such as expense, fitness of the patient to travel, availability of competent medical guidance, food and sanitary arrangements, and mental effect of the proposed new environment.

Pelvic Infections in Women.—Thomas J. Watkins (*Jour. A. M. A.*, October 7, 1916) confirms, in his own experience, the recent advances in our knowledge of infection and immunity which have resulted in most satisfactory methods of treating acute pelvic infections, but with few exceptions the best results have been secured from medical treatment alone. This should comprise fresh air and abundant feeding, which are even more valuable in these conditions than in tuberculosis. Adequate rest, sleep, elimination, and general hygienic measures cannot be too highly valued, and far surpass stimulants, tonics, etc. It is also of decided importance to keep the patient in a cheerful frame of mind, a condition of greater therapeutical value than many remedies advised. Blood transfusion or the subcutaneous injection of whole blood is of great value in selected cases. Curettage in puerperal and nonpuerperal infections is contraindicated, as it is likely to aggravate the condition and lead to a spread of infection. In the majority of acute cases, recovery under such medical treatment is continuous and rapid, there is little danger to be feared and the exudates are completely absorbed. Incision and drainage should be limited to cases with large, superficial, fluctuating abscesses.

Treatment of Syphilis of the Central Nervous System.—Homer F. Swift (*American Journal of the Medical Sciences,* October, 1916) urges the importance of prophylaxis of syphilis of the central nervous system. The best preventive would be prophylaxis of syphilis itself, but this problem is not yet solved, and the next best is the proper treatment of the disease in its early stages. No case of syphilis should be released from treatment until the cerebrospinal fluid has been shown to be normal, in so far as pleocytosis and Wassermann reaction are concerned. Even with the present diagnostic methods and effective therapeutic agents, a fair proportion of the patients are poorly treated, and probably a majority of them are released without lumbar punctures. The failure of many patients to be followed until cured is due to several causes: 1. The patients fail to realize the importance of proper treatment in the prophylaxis of later disease and discontinue treatment; 2, there is still a surprising lack of facilities in dispensaries for the proper treatment of syphilis; 3, many physicians fail to realize the long systematic course that is required to eradicate the disease completely; 4, there are many cases of innocent syphilis and syphilis with slight, if any, early manifestations which go untreated and later develop into nervous lesions. A table is presented to show the percentages with which tabes, paresis, and cerebrospinal syphilis have developed under different conditions of treatment. In practically a quarter of the poorly treated cases paresis developed, contrasted with a little over three per cent. of those who were well treated. In from eleven to twelve per cent. of the poorly treated ones tabes developed, and in only about one fifth as many of those who were well treated. A single course of treatment seemed to increase the liability to the cerebrospinal form of the disease. Hence the modern intensive treatment of early syphilis is particularly indicated to prevent the involvement of the central nervous system. In many cases of the early forms of syphilis of the cerebrospinal axis, mercury, iodides, and salvarsan affect the course of the disease favorably, but they are apt to fail, and the disease tends to relapse. Intraspinal therapy then comes into play, and the problem has been to find some beneficial therapeutic substance which could be introduced repeatedly without injury to the nervous tissue. The four preparations mentioned as having stood the test of time are: 1. Serum obtained from patients shortly after intravenous injections of salvarsan; 2, serum to which small quantities of salvarsan have been added; 3, neosalvarsan in small quantities and weak concentration; 4, mercurialized serum. These are discussed at length, together with the technic of preparing and using autosalvarsanized serum. Treatments seem to be better borne if not repeated oftener than once in two weeks, especially in patients with tabes or spinal syphilis. In those with paresis or cerebral syphilis the intervals may be shorter. At times the interval should be lengthened. A certain amount of irritation always follows the introduction of any foreign substance into the subarachnoid space and the effect of this should disappear before the treatment is repeated. The treatment must not be pushed hard enough to depress the general health. Salvarsan treatment should always be preceded by a short course of mercury to prevent a possible Herxheimer reaction in the region of vital nervous centres. In tabes it is better to start with small intravenous doses of salvarsan, gradually increasing, and giving a treatment a week for six or eight injections. If at the end of this course the Wassermann reaction of the fluid is considerably weaker, a course of mercury may be tried, followed by another course of salvarsan, alternate courses being given with periods of rest until the fluid is brought to normal. When the strength of the reaction is only slightly altered in this way, the substitution of combined intraspinal and intravenous therapy will usually result in an improvement in the condition of the fluid. In a rapidly advancing case of tabes, or of optic atrophy, this combined treatment should be seriously considered at the beginning. Treatment must be individualized in syphilis of the central nervous system, and while a general plan should be followed in the various forms of the disease, each case may demand a certain deviation to meet peculiar conditions. Its objects are three: To cure the disease, to ameliorate the symptoms, and to prolong life. With the possible exception of paresis, all of these objects may be attained in most cases of syphilis of the central nervous system.

Diagnosis and General Treatment of Syphilis.—John A. Fordyce (*American Journal of the Medical Sciences,* October) says that while it is possible, theoretically, to formulate a treatment in the various stages of syphilis, as a matter of practice the best devised plan must preeminently be an elastic one, subject to the modifications called for by the susceptibility of the patient to the drugs and to intercurrent reactions which take place from time to time. In early active syphilis, salvarsan alone has been followed by neurorecurrences and monorecurrences, or early tertiary lesions. In cases of initial lesion, seen before the Wassermann reaction is positive, salvarsan may perhaps be given without such danger, but it is better to give the combined treatment rather than to rely on this drug alone to establish a complete cure. Fordyce gives a course of mercury with the salvarsan, the number and size of the doses of both agents depending on the sex, body weight, and general condition of the patient. The salvarsan is given in courses of five or six injections in doses of 0.3 to 0.5 gram for men, and 0.25 to 0.4 for women at intervals of a week to ten days. The mercurial injections are given every day or alternate day, if a soluble salt is employed, once a week if an insoluble one. The soluble salt he prefers is the bichloride, in courses of twenty to thirty injections. The insoluble ones are gray oil, of which five minims represent one grain, or salicylate of mercury in doses of one to three grains gradually increased; ten to twelve injections constituting a course. Both salvarsan and mercury are followed by a rest period of six weeks, and then the procedure is repeated. Wassermann tests are made periodically, but treatment is not interrupted because of a negative reaction until the adequate amount of medication has been given. Thus it is possible to abort the infection both clin-

ically and serologically. When visceral lesions are present, salvarsan should be used in small doses repeated at intervals determined by each case. In cardiac conditions it is better to precede with mercury, or mercury and potassium iodide. In secondary syphilis with a positive Wassermann it is frequently necessary to give three courses of salvarsan with mercury before the desired effect on the serum reaction is obtained. In tertiary syphilis, the method of treatment depends upon the tissues or organs involved. It is of advantage to combine the courses of salvarsan with intramuscular injections of mercury, and to follow this with the prolonged use of potassium iodide and mercury in the form of mixed treatment. In so called latent syphilis, salvarsan often fails, and more benefit is likely to be obtained from the old fashioned mixed treatment. In secondary syphilis when the early rash is present and the Wassermann positive, it is better, on account of economy of time, to precede the salvarsan with several injections of a soluble mercurial salt. In tertiary syphilis with a persistent positive Wassermann reaction, without involvement of the central nervous system, the beneficial effects of potassium iodide cannot be too strongly emphasized.

Treatment of Diphtheria.—Deléarde (*Bulletin de l'Académie de médecine,* September 5, 1916) strongly advises that the doses of antitoxin given in diphtheria be large ones. In his clinic all children admitted, of whatever age, immediately receive sixty c. c. of the French standardized antitoxin if pharyngeal manifestations exist and eighty c. c. if there is croup. If the bacteriological diagnosis is confirmatory, the dose is made, in the twenty-four hours following admission, eighty c. c. in the presence of diphtheritic angina, and one hundred c. c. in the event of laryngeal involvement. Ten years' experience with this dose has shown it to be free from all danger and successful in its results, while admittedly a twenty c. c. to sixty c. c. dose is sufficient for diphtheria occasioned by the short variety of the bacilli, and in the absence of laboratory facilities an initial small dose can be increased in the event of poor results. Deléarde prefers to inject one or two massive doses, sufficient to insure rapid recovery, than repeated smaller amounts. Sudden deaths in malignant cases from myocarditis, as well as from massive albuminuria, postdiphtheritic paralysis, and prolonged convalescence, are thus avoided. Repeatedly he has seen a copious albuminuria diminish in one day upon injection of eighty c. c. or 100 c. c. of antitoxin. The reduction in the number of doses given—rarely exceeding three in number—lessens the chances of local infection and serum reactions, and spares the feelings of young, timorous patients. False membranes readily liquefy and are rapidly eliminated under the high dose treatment. Where the latter is begun when slight stridor already exists, the necessity for subsequent intubation or tracheotomy is removed. If, owing to late application of treatment, intubation has been required, high dose antitoxin therapy nearly always permits removal of the tube within forty-eight hours, thus avoiding the pulmonary complications which attend protracted presence of the tube.

Nail Extension in Fractures of Lower Extremity.—John C. A. Gerster (*Jour. A. M. A.,* October 14, 1916) concludes from a considerable experience that nail extension with the proper technic is a safe and useful measure. It is of particular value in simple fractures with extensive abrasion of the surrounding soft parts, in recent compound fractures with greatly damaged soft parts, in multiple fractures of one limb, in osteotomy cases, and in certain cases of operative reduction. The method, however, must not be made routine, but should be restricted to selected cases where it constitutes a valuable addition to the older methods.

Magnesium Sulphate Anesthesia in Man.—Charles H. Peck and Samuel J. Meltzer (*Jour. A. M. A.,* October 14, 1916) report the records of three cases in which surgical operations were performed under exclusive magnesium sulphate anesthesia. The drug was injected slowly and nearly continuously into a cubital vein. Six and ten per cent. solutions were employed, but the latter seemed too concentrated and caused temporary failure of respiration for ten minutes, during which time life was maintained by artificial respiration. The injections were made at rates varying from eight to fifteen mils a minute; but at times the latter rate was more than doubled for short periods. In each of the patients full anesthesia was secured and maintained throughout the operation, and in each recovery was prompt and without symptoms. In addition to the anesthesia the drug caused a satisfactory degree of muscular relaxation. These observations not only confirmed the belief that magnesium sulphate was an anesthetic, but also suggested its possible practicable and advantageous employment for this purpose in man. It had no ill effects, and an overdose, if given, could at once be antagonized by the administration of calcium chloride.

Magnesium Hypochlorite in Surgery.—M. Dubard (*Bulletin de l'Académie de médecine,* August 22, 1916) points out that the alkaline hypochlorites used in the form of Javelle's or Labarraque's fluid, are caustic chiefly because of the alkalies, not because of the chlorine. Magnesium hypochlorite is advantageous in that magnesium is practically non-irritating. The salt is nevertheless strongly bactericidal, its concentration can be varied much more readily than that of Dakin's solution, and it never produces any harmful effect on the tissues. It may be prepared either by the interaction of calcium chloride and magnesium sulphate or by direct action of chlorine upon magnesium hydrate, the latter procedure, according to Vaillant, yielding the purer product. Practically, no solution having a chlorometric titre exceeding 2.5° or 3° should be made. The solution, being unstable, should be freshly prepared before use. It causes no pain, and does not injure the hands even in much stronger solutions. Streptococci, staphylococci, colon bacilli, etc., are killed by two to four minutes' exposure to a 1.5° to 2.5° solution, while the spore-forming Bacillus subtilis is killed in eight minutes. In sterilizing the hands results better than those attending the use of tincture of iodine are obtained. A six to eight minute dip in a 2° solution removes all cultures from the skin surfaces. Clinical observations with a 1°

to 2.5° solution in the treatment of wounds showed that the compound yields results far superior to those obtained with Dakin's fluid. Its use in obstetrical practice is also recommended.

Trichinosis.—J. B. McNerthney and William B. McNerthney (*Jour. A. M. A.*, October 7, 1916) cited a severe case of trichinosis of fifteen weeks' duration which was promptly cured by a single intravenous dose of 0.6 gram neosalvarsan. Improvement began in forty-eight hours and recovery was nearly complete after two weeks. This experience is directly opposed to statements recently made concerning the value of neosalvarsan in trichinosis and its unfavorable effects in such cases.

Bipolar Ionization in Inoperable Carcinoma.—G. Benton Massey (*Medical Record*, September 30, 1916) describes the technic as consisting of the insertion of the active needles just beyond the periphery of the growth, while the indifferent negative electrode is inserted in its centre, thus confining the current with its chemical and thermal activities to the growth itself and to its edges. Both positive and negative electrodes are made of zinc, and in this bipolar method heat is merely accessory to the electrochemical destructive process.

Transfusion of Citrated Normal Blood in Acute Poliomyelitis.—G. A. Rueck (*Medical Record*, September 30, 1916) reports three cases treated successfully by the transfusion of blood taken from healthy adults and prepared with two per cent. sodium citrate solution. This treatment is based on the immunity of most healthy adults and children to the disease, the presence of antibodies in the blood of most persons, the rapidity with which transfused blood reaches the brain and spinal cord through the blood stream, the retention of phagocytic cells in whole blood, and the action of adult whole blood as a protective agent in most infectious diseases of children.

Treatment of the Discharging Ear.—Albert Bardes (*Medical Record*, September 30, 1916) writes that beginning otitis media may frequently be aborted by an ice bag, a mild cathartic, fluid food, rest, and hourly irrigation of the ear with a warm boric acid solution. Earache should not be allowed to last longer than twelve hours before incising the drum, and this should always be done under general anesthesia and preferably under chloroform. After incision, ordinarily it is simply necessary to keep the ear dry and clean, and irrigations should be used sparingly or not at all. A saturated solution of boric acid with some alcohol added makes a good lotion. The use of ear drops without an exact diagnosis of the nature of the lesion is unscientific, and hydrogen peroxide is especially contraindicated. Persistent discharge may require stronger applications, such as a twenty per cent. solution of iodine or a ten per cent. solution of chromic acid. The radical mastoid operation of Stacke is of value only in selected cases, and the best statistics show only fifty per cent. in cures. A better operation in most cases is the Schwartze operation, with removal of the mastoid cells and the establishment of free connection between the mastoid antrum and the tympanic chamber.

Impregnation of Cloth with Antiseptics.—Mary Davies (*Lancet*, September 30, 1916) has found after experimenting with a number of antiseptics that underclothing could be impregnated successfully with a five per cent. solution of pyxol, which consists of a saponaceous compound of cresols and soft soap. Such impregnation was inexpensive, nonirritant to the skin, did not damage the undergarments, and was inoffensive in odor. Cloth so saturated and exposed to the sun and rain for a month might be contaminated with the organisms of the soil in large amounts and yet when introduced into the tissues of a living animal the pyxol greatly inhibited the growth of the organisms so that only a small local abscess formed. The adoption of some such plan for soldiers is suggested in order to reduce the dangers of infection from imbedded pieces of clothing and to diminish the severity of infections when they do occur. Such impregnation might prove useful also in preventing infestation with lice.

Cranial Fractures.—Albro L. Parsons (*American Journal of Surgery*, October, 1916) points out that the technic of cranial surgery requires no further amplification, but there are certain features upon which greater emphasis might be placed. The prevention of infection by the most rigid adherence to modern principles of asepsis is one of the primary essentials to a successful outcome. In compound fracture the wound should be thoroughly cleansed before invading the cranial cavity, to minimize the danger of infection from without; if extensive cerebral laceration has occurred, after elevating or removing the damaged osseous structure, the cerebral tissues so devitalized as to be beyond hope of repair should be carefully excised. Adequate provision for drainage is imperative in every instance where the dura is incised, which should be always done if there is evidence of increased subdural pressure. A decompression operation without dural incision rarely accomplishes the desired result.

Intussusception.—Clarence L. Starr (*Canadian Journal of Medicine and Surgery*, October, 1916) advises operative treatment at the earliest possible moment. If seen immediately after the acute onset, an effort should be made to disengage the intussuscepted bowel. This may be done by inverting the child, raising the hips high and almost standing the child on its head, and by injecting water or saline into the rectum. The injection of metallic mercury is not to be recommended, nor should the bowel be distended with gas or air. If the patient is seen during the first twenty-four hours, it is usually possible to reduce the intussusception. An incision long enough to admit the hand should be made in the right rectus above the umbilicus. The mass is brought out without removing the remainder of the intestine and the reduction should be made with extreme care. It should be squeezed back from above. It is rarely necessary to stitch the bowel to the abdominal wall. If reduction fails, a rapid resection of the invaginated mass should be performed. If the patient's condition is very bad, it may be better to remove the mass by a rapid resection between intestinal clamps and then bring both ends out on the wall by means of a Paul tube.

Toxemia of Pregnancy.—Frederick T. Hyde (*Northwest Medicine,* Aug., 1916) recognizes the close relationship existing between the sexual functions and the organs of internal secretion—especially the thyroid. He has tried the administration of this gland in hyperemesis gravidarum and eclampsia. Only three patients, so far, have been treated thus, but the results were strikingly favorable, as is shown by their case records. One was a case of hyperemesis, the others of eclampsia. Thyroid was given in doses of 0.2 to 0.3 gram twice daily.

Radium Treatment in Hypertrichosis.—M. L. Heidingsfeld (*Lancet-Clinic,* September 23, 1916) reports a case of extreme hypertrichosis in which, at each of three points over which an application of radium had been made, the hair was completely and apparently permanently removed. Most of the heavy growth over the neck and chin, almost as marked as in an adult male, had already been eradicated. The radium treatment is painless, rapid, and effective, and the cosmetic result is far better than that secured with the only other trustworthy procedure—the needle and galvanic current.

The Results of Operative Treatment of Exophthalmic Goitre.—Vernon C. David (*Annals of Surgery,* October, 1916) summarizes: In sixty-five patients operated on for exophthalmic goitre from 1905 through 1914, thirty-eight per cent. were cured and forty per cent. were greatly benefited. Of thirty-five patients having exophthalmos before operation only thirteen, or thirty-seven per cent., reported themselves as relieved from it. The duration of symptoms before operation in the patients cured was sixteen months; in those greatly benefited, twenty-three months, and in those not improved, thirty-three months.

Postoperative Treatment of Gallbladder Surgery.—R. L. Rhodes (*Surgery, Gynecology and Obstetrics,* October, 1916) says that during the first few days following operation hexamethylenetetramine is given by proctoclysis because the patients are not allowed fluid by mouth, and to avoid any possibility of upsetting the stomach. After the first week it is given by the mouth. The drug is given five days each week and omitted for two days to prevent untoward symptoms; however, the drug is omitted for a day or two and then administered again should these develop earlier.

Examination of the Larynx.—N. Schoolman (*Journal of Ophthalmology and Oto-Laryngology,* June, 1916) states that chronic hoarseness, especially in men past forty years, should make a laryngoscopic examination an imperative duty to all practitioners. In the majority of cases hoarseness is the only evidence of beginning carcinoma for a long period of time—from one to three years. The symptom of pain appears in the later stages of the disease and is characterized by sloughing and ulceration. It is manifested in the form of otalgia, occurring spontaneously or during the act of swallowing, darting from the larynx to the ear, to the angle of the jaw, and to the back of the neck. Early examination of the larynx in the presence of a persistent cough may detect beginning tuberculosis.

Benzol and X Rays in Splenomedullary Leucemia.—Edmund Myers (*Northwest Medicine,* September, 1916) reports the detailed record of a severe case to show that neither x rays nor benzol alone is sufficient in some instances to control the disease, while the two may be effective when given simultaneously. The benzol was given in doses up to four mils daily, and the x rays were applied in turn to the ends of all of the large long bones and to the spleen.

Lumbar Puncture in the Fetus during Podalic Extraction.—Romolo Costa (*Gazzetta degli ospedali e delle cliniche,* September 3, 1916) asserts that this measure, with removal of cerebrospinal fluid, increases the power of moulding the head of the child and relieves the cerebrospinal pressure. Thus there is less difficulty in extracting the head on the one hand, and fewer asphyxiation symptoms on the other. Therefore lumbar puncture is advisable, in the interest of the fetus, in suitable cases of pelvic contraction and of insufficient cervical dilatation. The procedure is easily and quickly accomplished.

Modern Treatment of Burns.—George de Tornowsky (*Journal of Cutaneous Diseases,* March, 1916) states that in burns of the first degree the part should be gently cleansed with commercial ether and a sterile sponge; following this an ointment of white precipitate, one half dram to equal parts of zinc oxide and cold cream ointment should be applied with a sterile pad and bandage. The dressing should not be removed for eight to ten or even twelve days, unless there is great pain or elevation of temperature. In burns of the second degree, if the patients are in the hospital, the best results are to be obtained by exposing the part to the air, augmented by the use of a bland powder, such as stearate of zinc. In private practice this method cannot be employed and the two methods of choice are the amniotic grafts or white precipitate ointment. The amnion method is open to the objection that it locks up secretion. Where skin grafting is to be resorted to, it must be done early to get the best results.

Value of Various Diagnostic Methods for the Cerebrospinal Fluid.—H. Nakano (*Journal of Cutaneous Diseases,* March, 1916) draws the following conclusions: 1. The Wassermann reaction in the spinal fluid in late syphilis, as well as in cerebrospinal lues, tabes and dementia paralytica, rapidly disappears, but the serum reaction remains for a long period. 2. The substance causing the complement fixation in the spinal fluid probably enters the fluid from the blood, but we are unable as yet to determine whether the antibody of this reaction is produced in the fluid itself. 3. The Nonne reaction frequently appears in the cerebral and spinal diseases. 4. The Weil-Kafka reaction appears in acute and in chronic inflammations of the cerebrospinal and meningeal diseases. 5. The Lange reaction appears in all cerebral and spinal diseases. The nature of the Lange reaction is closely connected with the presence of globulin and nucleoprotein in the fluid. 6. The Nonne, Wassermann, Weil-Kafka, and Lange reactions disappear by degrees under treatment with salvarsan, mercury, and iodine.

Miscellany from Home and Foreign Journals

Diphtheria Bacilli in the Tonsils of Carriers.—Mary Brown (*Journal of Infectious Diseases,* October, 1916) calls attention to the fact that the tonsils may be the source of infection in diphtheria carriers. The tonsils of seven diphtheria carriers were studied, six of whom had had pharyngeal diphtheria, and one of whom was a carrier without symptoms of intoxication. Of these, six tonsils showed Gram positive beaded bacilli in great numbers. The one case which showed no bacilli in sections of the tonsils or adenoids gave positive cultures from the nose for nineteen days after tonsillectomy. Of the fourteen pairs of control tonsils, only two showed any Gram positive bacilli. The results would indicate that an important focus of infection is removed when tonsillectomy is done upon diphtheria carriers.

A Rapid Method for the Diagnosis of Renal Tuberculosis by the Use of the X Rayed Guinea-pig.—Morton (*Journal of Experimental Medicine,* October, 1916) undertook certain experiments to determine whether or not the time taken for the development of tuberculous lesions in the inoculated pigs might not be shortened. He found that guinea-pigs could tolerate a large amount of x rays without apparent injury to their health. The chief action appeared to be a marked reduction in the number of lymphoid cells. By exposing the animals to a single massive dose Morton noticed that a diagnosis could be made in the inoculated pigs in from eight to ten days instead of having to wait five to seven weeks. The x ray may be used either shortly before or after the inoculation of the material to be tested.

Antidotes in Mercuric Chloride Poisoning—An Experimental Study.—Bernard Fantus (*Journal of Laboratory and Clinical Medicine,* September, 1916) as a result of his studies recommends the following antidotal treatment for mercuric chloride poisoning. The immediate administration of an antidote, either Carter's, which is a tablet composed of sodium phosphate, 0.36 gram, and sodium acetate, 0.2 gram, or if this be not available, the following: Sodium hypophosphite, one gram; water, ten mils; hydrogen peroxide, five mils. If the amount of poison taken be known, ten times as much of the hypophosphite should be given as poison was taken. As this might require a large and possible harmful amount of hypophosphite, it should immediately be followed by copious lavage, with a very dilute solution of antidote. This may be followed by a safe dose of the antidote, which is to be retained, and which might be repeated every eight hours for several days. This antidotal treatment may be combined with some such treatment as that recommended by Lambert and Patterson, excepting that sodium acetate is preferred to the potassium bitartrate given by stomach, because of its superior antidotal power. Egg albumin is of little value as an antidote to mercuric chloride, unless it is given immediately after the poison is swallowed. Milk and serum albumin are worthless. Hall's solution (potassium iodide and quinine) is also useless.

Bacillus Isolated from Epileptics.—William Barclay Terhune (*Jour. A. M. A.,* October 14, 1916), with the purpose of testing the claims recently made by C. A. L. Reed, and starting with the idea that epilepsy was not of bacillary origin, took blood cultures from a series of twenty-four epileptics and obtained positive cultures in seventy-five per cent. of the cases. The organism isolated was similar to that described by Reed. It was not a constant finding, the same case often giving positive and negative results when examined on different occasions. It was present, when found, during or after a seizure, but was only once found during an interval. It was absent from nonepileptics. It was also found to produce typical epileptoid attacks in cats, both after intravenous inoculation and after feeding them with the cultures. After the death of these animals or during the convulsions the organism could be recovered from their blood In one instance a cat kept in the same cage with those which had been inoculated, exhibited spontaneously similar convulsive manifestations and died, suggesting the possibility of the direct transmission of the germ, probably through feces.

Hammer Hand and Plantar Hand in Ulnar Paralysis.—Hesnard (*Paris médical,* August 26, 1916) calls attention to a deformity of the hand resulting from traumatic paralysis of the ulnar nerve, characterized by an anterior projection of the metacarpophalangeal joints, with a corresponding depression across the dorsum of the hand, and also generally a clawlike position of the fingers, the hand seen in profile, thus presenting an S shaped curve resembling that of a swan's neck. This deformity, which he terms "hammer hand" because of its similarity to hammer toe, is most pronounced at the little finger, diminishing as one proceeds outward, with the thumb escaping entirely. The deformity generally appears only several months after the injury to the ulnar nerve, and is sometimes incomplete or, rarely, absent. In its incipience there exists merely a slight metacarpophalangeal prominence anteriorly, which imparts to the hand an appearance somewhat like that of the sole of the foot with its two heels, anterior and posterior; hence the term "plantar hand" applied to it by the author. The deformity, in its two stages, is of distinct value as a diagnostic sign of ulnar nerve paralysis, as there are cases in which it positively reveals injury to this nerve in the absence of many other signs, such as loss of function of the hypothenar muscles, or sensory disturbances; or in which, because of vicarious functioning of other muscles, paralysis of the adductor of the thumb cannot be made out. The cause of the deformity is a simultaneous hypertonicity of the extensor and flexor muscles governing the fingers, together with the diminished tone of the lumbrical and interosseous muscles. The deformity may exist even in cases in which the nerve is not injured beyond spontaneous repair, and may gradually pass off, though as a rule only incompletely.

Röntgenocardiograms.—A. W. Crane (*Jour. A. M. A.*, October 14, 1916) describes a comparatively simple apparatus for use with the x ray machine which permits the taking of cardiograms directly from both auricles and the left ventricle. The principle consists in making a narrow strip of the cardiac shadow at the margin of each of the heart's chambers record its own shadow upon a moving sensitized film. The tracing thus obtained is one of the actual movements of the heart's chambers and is not in any way altered by mechanical factors. By this method such conditions as auricular fibrillation and conditions in which there is regurgitation into one of the auricles are clearly shown. The method has many advantages over the graphic methods now in use and is at least a valuable adjunct to them. It may be used in combination with the other methods and the records may be simultaneously reproduced upon the same film.

Specificity of Streptococci.—Henrici (*Journal of Infections Diseases*, October, 1916) draws the following conclusions from his experiments in which fifty-three strains of streptococci from various sources were inoculated into 225 rabbits: The hemolytic streptococci are more virulent than the nonhemolytic, but the two classes localize in the same tissues with equal frequency. From evidence obtained by rabbit inoculation experiments, we are justified in recognizing any particular class of streptococci as specific for rheumatic fever, since the various rheumatic lesions, arthritis, myocarditis, endocarditis and myostitis, may be produced by some strains in each of the varieties, and are produced in equal proportion by both hemolytic and nonhemolytic streptococci. Streptococci of various kinds may produce, in rabbits, types of myocarditis which cannot be differentiated from the Aschoff-Geifel nodules generally considered diagnostic of rheumatism. Experimental streptococcal endocarditis develops by implantation rather than by embolism.

Absorption of Potassium Iodide by the Thyroid Gland.—David Marine and J. M. Rogoff (*Journal of Pharmacology and Experimental Therapeutics*, August, 1916) report a series of thirty-three experiments in dogs in which 0.05 gram of potassium iodide was injected into the internal jugular vein and the amount of the iodide in the thyroid compared with that found in a lobe of the thyroid removed before the experiment. The animals were killed at intervals varying from five minutes to thirty hours after the iodide injection. In all experiments there was a great increase of iodide in the thyroid lobe exposed to the drug. The absorption of the drug by the gland was, furthermore, so rapid during the first few minutes as to be practically instantaneous, the slight further increase in the long period experiments being hardly appreciable. The absorption varied directly with the degree of active hyperplasia of the thyroid present, and inversely with the original iodine content of the gland. Pieces of liver and spleen from the same animals showed no retention of iodine. Evidently the thyroid has an extraordinary affinity and other tissues but little affinity for iodine. Marine and Feiss have shown that artificially perfused thyroids rapidly take up potassium iodide in a similar way.

Bichloride of Mercury Poisoning from Vaginal Absorption.—A. F. Wilkie Millar (*Brit. Med. Jour.*, September 30, 1916) reports the case of a young woman, who inserted one tablet of bichloride, containing 0.57 gram of the salt, into the vagina, and twelve hours later began to complain of pain and swelling of the vulva. Immediate douching was ordered, but in a few hours the typical symptoms of severe bichloride poisoning had developed and these progressed to a fatal termination on the sixth day in spite of all efforts at treatment.

The Milking Machine as a Source of Bacterial Contamination of Milk.—Ruedegir (*Journal of Infectious Diseases*, October, 1916) points out definitely that the milk may be contaminated badly by a milking machine if the teat cups and rubber tubes are not carefully cleansed and scalded before each milking. He found that in warm weather, particularly, the milk obtained by a milking machine may give a much higher count than that drawn by hand. In one dairy the milk drawn by hand contained 860 colonies, by the milking machine as generally used over two million. When the same machine was used after thorough scalding of it and the can, the count was twenty-four hundred.

Bacteriology of the Public Fountain.—Pettibone, Bogart, and Clark (*Journal of Bacteriology*, September, 1916) in their article rather upset our ideas concerning the value of the ordinary bubble drinking fountain. They found that during an epidemic of streptococcus tonsillitis in a dormitory, streptococci were found in the bubble fountains in the building and in the water issuing from the fountains. In an experimental fountain they found that Bacillus prodigiosus remained in the water from two to 135 minutes, depending partly on the height of the water. In order to avoid the retention of bacteria they advise that the fountain, instead of being vertical, should incline at an angle of about fifteen degrees.

Vascular versus Interstitial Nephritis.—B. G. R. Williams (*Archives of Diagnosis*, July, 1916) points out that vascular nephritis or arteriosclerotic kidney, with its confusing urinary findings, is a far more common condition than frank interstitial nephritis, with its characteristic symptoms and urinary findings and rapid, hopeless course. The latter diagnosis should, in fact, be actually avoided where it is possible to diagnose vascular nephritis. The diagnosis must, moreover, be based not on the blood pressure or a single urine examination, but upon a series of uranalyses, checked by the symptomatology. Although textbooks state that the two conditions cannot be differentiated by the uranalysis, Williams found in a study of 20,000 samples of abnormal urine that it is possible in many cases to discriminate very accurately between the two conditions. In true interstitial disease there is a persistent polyuria, while in vascular nephritis the output is variable, sometimes increased, sometimes normal, and during the "crises," in which a subject in apparently good health suddenly shows grave symptoms, with loaded urine, there is usually oliguria. The specific gravity, usually persistently very low in interstitial nephritis, is usually normal

or slightly low between crises in vascular nephritis, and usually low, less often high, during a crisis. Whereas in interstitial disease the reaction of the urine is usually slightly alkaline, in vascular nephritis it is usually excessively acid early in the disease, while later there is persistent and marked alkalinity. Albumin, casts, degenerative granules, and renal cells in interstitial disease are generally present in slight, but almost stationary amount. In vascular nephritis, the microscopic findings are practically negative between crises, while during a crisis large quantities of albumin and casts may be present. In vascular nephritis a prognosis should be avoided, even with the patient panting, nauseated, or comatose, with little or no passage of urine loaded with casts and albumin. The author has seen a man seventy-five years old, with an extended renal history, recover and return to his desk for two more years.

Transient Auricular Fibrillation. — E. B. Krumbhaar (*Archives of Internal Medicine*, August, 1916) reports a detailed study, with the electrocardiograph, of six patients in whom a change from the normal rhythm to auricular fibrillation occurred. He divides cases of auricular fibrillation into three groups: 1. In an acute infection, such as pneumonia or septicemia, or an acute intoxication, as in alcoholism or hyperthyroidism, attacks of fibrillation sometimes occur for several days, probably independently of any myocardial damage. 2. In a group probably always associated with myocardial degeneration, paroxysms lasting from a few minutes to many hours or even days may be induced by one of a great variety of causes, the condition, however, eventually tending to become permanent, though death may occur before this stage has been reached. 3. In a group with prominent signs of valvular or myocardial disease, the original appearance of fibrillation is apt to be permanent, or preceded by only a few transient periods; in such cases pulmonary embolism, acute pericarditis, or pregnancy may be the factor determining the advent of the fibrillation. Rest in bed, the digitalis group of remedies, and the removal of sources of intoxication, assist in terminating attacks of fibrillation, but excessive amounts of digitalis may help to bring it on.

Race, Sex, and Age as Factors in the Incidence and Prognosis of Pellagra.—J. F. Siler, P. E. Garrison, and W. J. MacNeal (*Archives of Internal Medicine*, August, 1916) report conclusions reached in an extensive field study of pellagra in Spartanburg County, S. C. The incidence data, comprising 1,180 cases, are based only on cases in which the initial attack was known to have occurred during the period of study. The incidence per 10,000 individuals was 231 for white females, 103 for white males, eighty-one for colored females, and twenty-five for colored males. The disease was rare under the age of one year, but fairly common in the age period from two to twelve years. The age period of twelve to sixteen years was relatively free from initial attacks. After sixteen, the incidence rose rapidly in women up to the age of twenty, then gradually diminished; the number of men attacked, on the other hand, gradually increased all along, so that the incidence in the two sexes was practically the same at fifty years. There was usually clear evidence of residence very close to an antecedent pellagrin in the cases of infantile pellagra; the milk of pellagrous mothers, however, cannot be regarded as a cause or vehicle of transmission. Curiously, the lower incidence rate among negroes coincided with greater poverty of this race and a diet poorer in quality, quantity, and variety. Incidence was lowest in the sex and age groups of negroes most completely segregated from white pellagrins. The death rate in the year of the initial attack was 15.8 per cent. for the entire series—12 per cent. in the white race and 41.8 per cent. in the negroes. The death rate among white women over twenty years of age was 11.9 per cent.; among white men, 21.2 per cent.; among colored women, 40.2 per cent., and among colored men, fifty per cent. In all groups there was a tendency for the death rate in the initial attack to increase with age. Among children the death rate in initial attacks was low.

Tests for Normal Cardiac Power.—Camille Lian (*Bulletin de l'Académie de médecine*, September 5, 1916) makes the statement that in military practice, great difficulty has at times been experienced in deciding, even after all varieties of examination had been gone through, whether men were or were not fitted for active service. Lian has found, however, two tests of constant value. Both are based on counting the pulse after an exactly measured physical exercise. The first test consists in having the subject, after the pulse rate at rest in the standing position has been carefully ascertained, execute running steps on one spot, with the legs bending to a right angle with the thighs, at the precise rate of two steps a second. At the end of one whole minute the subject stops and remains at rest standing, while the pulse rate is counted for fifteen seconds in every minute—beginning at once when the exercise stops—until it returns to normal or nearly so. The heart is considered adequate for military exertions when the rate returns to normal or nearly so at the beginning of the second or third minute after the termination of the exercise. A rise in the rate to over thirty in fifteen seconds, from the normal resting rate of seventeen to twenty-two, is held to show slight cardiac weakness. Where the rate rises as high as thirty-eight and returns to normal only after four or five minutes, heart weakness is so distinct that the subject must be relieved of the more arduous military duties, while if it rises to forty-two and lasts six or more minutes, the subject should leave the front, as he is fitted only for auxiliary service. The second test occasionally reveals cardiac weakness which the first failed to show. The subject, while standing, raises a five kilogram weight over the head, then brings it down between the legs with the body bent forward and lower extremities flexed. This is continued for one minute at the rate of five or six cycles in every ten seconds. The results are interpreted as in the first test. The details of these tests must, of course, be somewhat modified in the examination of women and children.

Factors in the Production of Cardiac Dyspnea.—Francis W. Peabody (*Jour. A. M. A.*, October 14, 1916) reports that three distinct but more or less related factors emerge from a study of the causation of cardiac dyspnea. The most important and constant seems to be a decrease in the vital capacity of the lungs. In severe cases there may be in addition more or less acidosis and to a less extent an increase in body metabolism.

Comparative Study of Tests for Renal Function.—Herman O. Mosenthal and D. Sclater Lewis (*Jour. A. M. A.*, September 23, 1916) has made a series of comparative observations to determine the relative values of several renal functional tests which led to the construction of a table to indicate the scale of impairment. Regarding the tests themselves, it was found that the earliest indication was given by the test meal-specific gravity test; next in order of positive results was the phenolsulphophthalein test; then Ambard's coefficient; and finally the determination of blood urea. Indication of a maximal disturbance of the kidney function was most often given by the test meal, less by phenolsulphonephthalein and least often by Ambard's coefficient. Owing to the external factors producing death in nephritis, the relative prognostic value of the functional tests was found to be uncertain. However a nonprotein blood nitrogen of over ninety mgm. or a blood urea nitrogen above sixty-five mgm. seemed to be the most trustworthy signs of fatal outcome. An Ambard coefficient of 0.2 or higher was also usually an index of a fatal ending in a few months. There was, however, no infallible prognostic test. In cases with marked anemia a condition was often encountered in which there was a dissociation of renal function and there the results of one or more tests might be positive, while those of others indicated normal function. From this study also, it was evident that each test covered only a limited range of renal activity and that none measured the function as a whole.

Radical Abdominal Operation for Carcinoma of the Cervix uteri.—Comyns Berkeley and Victor Bonney (*Brit. Med. Jour.*, September 30, 1916) reports the performance of a radical operation, consisting in the total removal of the uterus in a bag consisting of the upper half or two thirds of the vagina, the ovaries, tubes, broad ligaments, the parametric and paravaginal tissues down to the levator ani and the glands in the obturator fossæ and along the internal and external iliac vessels. From 1907 to 1911 a total of 100 cases were thus operated in, and the ultimate results of all of the cases, except seven which could not be traced, are here given. The operability rate, based upon all cases presented was about sixty-two per cent., and the immediate mortality from the operation was twenty per cent. If the seven cases lost sight of are deducted there were forty-two per cent. of cures for five years, and if the patients dying of the immediate operation and two which died of intercurrent diseases also be deducted there were nearly fifty-five per cent. of permanent cures. Of all cases originally presenting themselves for operation there were twenty-four per cent. of cures. This was a very high proportion of cures, particularly when it is borne in mind that thirty-five per cent. of the cases had malignant involvement of the glands. In the group of 100 cases there were thirty-two recurrences, twenty of which happened within the first two years after operation. Lastly, of the entire group of cases operated in sixty-one per cent. had some prolongation of life as a direct result of the operation.

Weil's Disease.—Adrian Stokes and John A. Ryle (*Brit. Med. Jour.*, Sept. 23, 1916) state their experience with several typical cases of Weil's disease, as encountered among the troops in Flanders, which confirmed the recent findings of Japanese and German investigators. From two early cases guinea-pigs were successfully inoculated, and in their tissues the typical spirochetes were found in great abundance. In addition, the same spirochetes were found in blood from one of the human cases after citration and centrifugation.

Etiology of Cholecystitis and Gallstones and Their Production by Intravenous Injection of Bacteria.—Rosenow (*Journal of Infectious Diseases*, October, 1916) gives in detail the results of his experiments in which he was able to produce marked lesions in the gallbladders of his animals by means of streptococci and colon bacilli injected intravenously. The organisms used had been obtained from human galibladders. Of the animals injected, in seventy-nine per cent. lesions of the gallbladder developed. Definite formation of gallstones was found in six rabbits and three dogs. From his experiments Rosenow holds that in addition to an infection furnishing the nucleus for the precipitation of the bile salts, it is necessary to have a concentrated bile of high cholesterinol content.

Spontaneous Liberation of Epinephrine from the Adrenals.—G. N. Stewart and J. M. Rogoff (*Journal of Pharmacology and Experimental Therapeutics*, September, 1916) designate as a spontaneous liberation of epinephrine from the adrenals, a liberation taking place under experimental conditions in the absence of artificial stimulation of the splanchnic nerves. It is not implied that this liberation is necessarily a physiological process and is not excited merely by the abnormal sensory stimulation, anesthesia, and other factors, connected with experimental work in animals. The question was studied in cats by a new method, viz., the blood pressure changes caused when blood from the adrenals is allowed to pass into the general circulation from a pocket of the vena cava in which the blood has been collected in a known amount for a known time. The amount of epinephrine liberated was found to vary in different experiments within a rather narrow range—from 0.0008 to 0.0028 mgm. a minute for each animal (or, from 0.0003 to 0.001 mgm. a minute to each kgm. of animal). After section of both sympathetic trunks in the thorax near the diaphragm, including the major splanchnic nerves, the spontaneous liberation of epinephrine was completely abolished. No increase in epinephrine liberation was detected when sensory nerves were stimulated. Although cats survive indefinitely the removal of one adrenal and division of the nerve supply of the other, no epinephrine was found in the blood coming from the remaining adrenal in such animals five weeks after the operation.

Proceedings of National and Local Societies

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting Held May 4, 1916.

The President, Dr. WALTER B. JAMES, in the Chair.

Some Disorders Supposed to Have an Emotional Origin.—Dr. WALTER B. CANNON, professor of physiology, Harvard Medical School, reviewed the results of a few of his experiments, some of which had already been published in book form, in relation to the bodily changes that accompanied some of the stronger emotions such as fear and rage in human beings and in the lower animals. These mental upheavals, which they shared with the lower animals, had characteristic expressions which were so well known that they made a common language between man and animal, namely, erection of hair, dilatation of pupils, great acceleration of the heart action, interference with secretory function, stoppage of movements of stomach and intestines, and muscle tension. There was, in these surface manifestations of the emotional state, definite interpretation of what was going on in the mind. These studies brought out some interesting facts in regard to the relation between these emotions and the glands of internal secretion.

The consideration of how the emotional states worked out in pathological conditions involved a consideration of the nerve pathways which were passed over by the impulses which brought about the surface manifestations. The relation of these pathways was made clear by the lantern pictures of the anatomy of the sympathetic nervous system. The adrenals were affected by the disturbed nervous state. Experiments were made to determine if there was oversecretion of adrenine in times of emotional excitement. Rhythmically contracting intestinal muscle which was relaxed by adrenine, one in twenty millions, was used as a test. Blood was taken from an animal when quiet and also when frightened. The blood of a cat, taken immediately after it had been frightened by the barking of a dog, was surcharged with adrenine; this was evidence that the adrenals did secrete in times of emotional excitement. When adrenine was injected into the body, there was an increase of sugar in the blood, and the question arose whether there was not always an increase in times of excitement. There was an excess of sugar in the urine, indicating an increased amount in the blood, when the cat was frightened. Adrenine, when injected, caused inhibition of the muscles of the alimentary canal and also sent blood away from the abdominal cavity, away from the stomach and intestines to other structures, in which the bloodvessels were not made to contract by injections of adrenine, such as the heart, lungs, central nervous system, and the skeletal muscles. These injections also caused an increased number of red blood cells and this was also the case in times of excitement. They also caused a faster clotting of blood. Profound bodily alterations thus accompanied the most elementary emotions, such as rage or aggression. The emotion of fear was associated with the instinct to run, the aggressive feeling with the instinct to attack. These were the emotions aroused in wild life in which there was likely to be a struggle for existence. They were closely related in their psychology. They both feared and wished to kill anything that could kill them, and the same bodily changes occurred in fear and rage. These instincts in a human being were related to all the others; all the others might be quickly changed into the two principal ones of fighting or escaping. A dog took his bone because he wanted to eat; if they attempted to take the bone, although the dog was ordinarily gentle and knew their greater power, he would likely nevertheless attack them. A mother, all tenderness for her child, would use all the force she could muster if anything attacked or hurt that child. Various emotions were easily transformed into the two underlying emotions, surviving for generations from the struggle for existence. These emotions were accompanied by the same bodily changes in animal and in man, including increased blood sugar. Students taking examinations might get so excited that there would be glycosuria. A few years ago, it was observed that half the men of a football squad had glycosuria after a game.

The key to the significance of these changes was to be found in relation to the necessity for struggle. The increase in blood sugar was due to the liberation of its store in the liver. It was a prime source of muscular energy. The alteration in the circulation sent the blood from the abdominal cavity, where activity subsided for the time being, to the heart, lungs, central nervous system, and muscles, the various structures brought into action in times of great excitement or struggle. The cessation of activity in the alimentary canal was part of a larger change, tending to make the entire organism more efficient. The early coagulation of the blood prevented loss of this precious fluid through injury to the vessels. In fact, all the changes could be accounted for on the basis of their being means of bringing about reinforcement of all the activities of which the body might find itself in need in the preservation of the organism as a whole. This activity of the adrenal glands could be called an emergency activity. They could in this way account for the great acts of power and great feats of endurance sometimes reported as accomplished in times of great excitement.

The question had been raised, why it was that the organism disturbed in times of emotional excitement was not disturbed at other times: why the pupils did not dilate or the heart beat rapidly or the secretions and motions of the stomach stop their activity. The failure of these disturbances to occur in ordinary life might be accounted for by there being, between the preganglionic fibres and the outlying neurons of the sympathetic system, a point of junction, the synapse, in which there was considerable resistance to the passage of impulses over or through it, and it was necessary to have a great deal of stimulation in the central nervous system, a great deal of excitement in order to cross the threshold.

This conception could be used to account for the indications, in pathological states, of frequent and continued disturbances in these various structures —the heart, the stomach, etc.—for in these cases there might have been repeated emotional experiences which accomplished a wearing down of this threshold, or a wearing down here and there so that there would be an easy passage outward. The repeated transmission of impulses resulted in the wearing of pathways. There were what might be called breaks in the barrier. Thus they observed that an organ, normally brought into action only in time of great stress might be chronically disturbed, and this would account for nervous dyspepsia, inactivity of the stomach, a certain type of tachycardia, intestinal stasis or incontinence, or a persistent glycosuria of emotional origin.

Henry Rutgers Marshall, L. H. D., D. S., said that as a psychologist he looked at Doctor Cannon's experiments from a certain point of view, though their significance was general. Though he looked at the matter seriously, he could not resist the temptation to suggest that in future it was possible that directors of the drama would insist on their emotional artists being injected with adrenaline before a performance to insure the strongest presentation of rage, fear, anxiety, etc. His own point of view was influenced by reading Charles Darwin's *Expressions of the Emotions in Man and the Animals,* in which it was conclusively shown that the activities, commonly called the expression of the emotions, were instinctive activities that had been inherited because of their racial value. This point of view was very effectively corroborated by Doctor Cannon's experiments, and it was the view commonly held. Darwin, in the work referred to, accepted the common notion that the emotion caused the reaction, or expression, and in the title, Disorders Supposed to Have an Emotional Origin. Doctor Cannon seemed to agree with this. This deserved study, for it was not clear how instinctive reactions which arose automatically and immediately upon the receipt of a definite stimulus, could be caused by emotional states. William James held, on the contrary, that the instinctive reactions caused the emotions, which were what Lloyd Morgan had aptly called "back strokes," results of the automatic instinctive reactions called expressions. To put the matter in the vivid language which Mr. James used, "they did not flee because they were afraid, but they were afraid because they fled: they did not strike because they were angry, but they were angry because they struck." In other words, he held that the emotions of fear and anger, for instance, were afterresults of the purely automatic instinctive activities involved directly or indirectly with the running away, or with striking the enemy

In his more mature view, the speaker had come to believe that the causal relation was not involved at all between the mental and the physical. All that the evidence pointed to, was the existence of a strict one to one correspondence between the two. This was an important point and Doctor Cannon's experiments seemed to corroborate it. Some of the results of such a view, both physiological and psychological, he had attempted to point out in an article published in the April number of *Mind,* in connection with the study of retentiveness and of Bergson's and Freud's theories of dreams. Under such a view, it could no longer be held that there existed a causal relation between the emotion and its expression; there was no more warrant in saying with Professor James that they were afraid because they fled, than in saying with the common man that they fled because they were afraid. The most that they could say, was that the specific form of the instinctive action was a relatively immediate reaction to a selective definite stimulus and this was based wholly, or in large part at least, upon inheritance. Man displayed a countless variety of such instinctive actions, varying greatly in complexity. The extreme limit in one direction was the simple reflexes, and the so called emotional expressions were examples in the direction of complexity. Corresponding with the more complex instinct-actions, changes were noted in the consciousness which might be called instinct-feelings; these differed as the instinctive-actions differed. They felt such an instinctive feeling when quite automatically they rushed forward, and again when they jumped back suddenly to escape an automobile, and the instinctive feelings in the two cases were as distinctly different as the instinct-actions were distinctly different. Now most of their instinct-actions recurred but seldom in anything like a definite form. Certain of them, however, did recur frequently and were relatively constant in form. In such cases, they came to recognize them and describe them as Charles Darwin and Doctor Cannon had done. In like manner, the corresponding instinct-feeling recurred, for the most part infrequently in anything like a definite form; but some of them did and these were recognized and received names. In the speaker's view, it was the instinct-feelings of this latter type which were called the emotions. Thus it would be seen that this general conception taught that a definite type of behavior necessarily involved a definite attitude of mind and vice versa, and each change of a person's behavior necessarily involved a corresponding change of his mental attitude and vice versa. As nations were merely aggregations of individuals, this meant that definite changes of national attitude of mind necessarily went with changes of national habits of action; a fact, which, in the speaker's view, they were overlooking at the present moment. Under the view which he defended, the emotions, as types of mental states, could not be looked upon as casually related with what they called their expressions, but merely as symptomatic accompaniments of these instinctive activities. It made all the difference in the world which position they took. If the mental states were treated as casually related with physical states, the physician was tempted to step outside the real sphere of his work. While if mental states were treated as symptoms of physical states, the physician employed the mental states merely as aids to the discovery of such physical conditions as he was called upon to deal with.

The speaker was especially interested in the impressive evidence furnished by Doctor Cannon of the marvellously intricate coordination of minor

systemic parts necessary to the very existence of the high organisms; evidence that had been accumulating in large measure in the last decade and which led to the abandonment of the study of the physical organism as though it were a quasi atomical collection of separate organs, leading rather to the study of it as a whole system of enormous complexity in which each organic part had its place as a minor system. The biologist was thus coming daily to look upon problems relating to organization as of greater and greater importance, as was indicated for instance in the last book from the pen of the eminent English physiologist, Haldane. Correspondingly, in the realm of consciousness, psychologists had discarded psychological atomism and were treating the mind as an immensely complex system of psychic systems. This fact, that the physiological and mental structure and functioning were to be considered as single wholes, was surely often overlooked, on the physiological side, for instance, by those pedagogues who urged intensive specialization in any particular field to the abandonment of broad culture; they forgot that this specialization tended to involve a loss of such balance of judgment as was required if real advance in thought was to be made. It had led in the scientific world to a great amount of pleading which passed without protest. The physician could be said to have escaped altogether the dangers involved in the forgetfulness of the fact that each part of the body was essentially related to the system as a whole. It was certainly overlooked when a surgeon operated where there was no urgent need, and when there was at the time no little hope of a readjustment of function by natural processes which would leave the system intact and newly balanced.

No one who was impressed with the import of the facts brought to their attention by Doctor Cannon could be guilty of such thinking, and the speaker had dared to make these critical remarks because he felt that they could not possibly apply to those present, except as they might be urged to take note of them in the guidance of their pupils.

Dr. Charles L. Dana was not a physiologist and could only accept Doctor Cannon's data. He accepted also as most reasonable the theory of the mechanism of defense. He subscribed to the laboratory work and the deductions presented by Doctor Cannon, and did so in spite of a critical attitude which he had begun to feel toward laboratories in general. They were doing splendid and constructive work, but they were also enslaving and, in a way, enfeebling the clinician and, in addition, they were sending out occasionally misleading and incomplete announcements. The laboratory often needed a humanizing influence and should be more dominated by the clinical spirit.

The speaker had one practical suggestion to make bearing on Professor Cannon's observations: There were emotional states which came on acutely, but lasted very intensely for weeks and months. These were cases of acute mania, or hypomania, in which the patient was joyously exhilarated, alert, talkative, had violent outbursts of anger, and was intensely active physically and mentally under the pressure of the emotional state, which suddenly left him, or a contrary state of agitating depression occurred. These emotional states might be like those brought on by shock. The question whether they were brought on or kept up by periodical explosions of pluriglandular activity would be worth examining. It was well known that in hyperthyroidism there was often a distinct excess of emotional tone.

Dr. Joseph Collins said that Doctor Cannon's statements were acceptable and had been accepted. Those who were familiar with his book would recognize that a large part of what had been set forth at this symposium was contained therein with adequate substantial proof, not only by himself and his pupils, but by others. There was no room for criticism or argument; it remained, therefore, for any one like himself, in attempting to discuss the matter, to apply the findings to the clinical problems confronting him as a neurologist. Therefore, he asked himself, had there been anything in his clinical experience to warrant him in believing that diseases of the nervous system flowed from disordered emotions; did the primal, painful emotions, such as fear, anger, or jealousy cause nervous or mental disease? The answer was negative; his experience did not entitle him to the conviction that such emotions caused such diseases. Conditions which were adequate to produce an excessive secretion of the adrenal did not enter into the causation of functional nervous or mental diseases, nor was he convinced that emotional factors such as worry, fright, and what was called mental stress, had much to do with causing Graves's disease; the phenomena of that disease were aggravated by such emotional factors, but the disease was not caused by them. The theory which best explained most functional nervous and mental diseases, especially the obsessive and hysterical, was the theory propounded by Freud. Such diseases, or their manifestations, were often caused precipitately to disappear when the original trauma or injury was discovered and eradicated, appeased, or satisfied. Of course it might be that the psychic trauma existing in the subconscious might, through the medium of the painful emotions, cause a plus activity of the internal secretions and thus cause or maintain such physical accompaniments of disease as these neuroses and psychoses had.

Doctor Cannon and others, however, had pointed out that there was a decided antagonism between the emotions expressed in the sympathetic and the cranial and sacral divisions of the autonomic system; emotions expressed through the cranial and sacral autonomic were not those that provoked disease. It was only those which were expressed through the sympathetic which called forth the body's vital reserves, the stored adrenine and the accumulated sugar which might, as it were, become pathogenic. Perhaps it was that the effect of the emotions on the sympathetic on the one hand and on the cranial and sacral autonomic on the other, counterbalanced one another, and this explained why they did not have "emotional" diseases. The role played by the emotions in influencing diseases was quite another matter. The effect of anger, worry, or jealousy upon gout, nephrolithiasis, diabetes, and other diseases had long been recognized, and

the speaker thought it might be more profitable to try to apply Doctor Cannon's interesting and important findings to such diseases and to the great problem of acidosis, than to the functional nervous diseases.

Dr. Harlow Brooks said that Doctor Cannon had given the explanation for conditions that had long been recognized. Clinicians had long known of the significant effect of the emotions on organic disease: there was not one who did not realize the great influence of the emotions in the etiology of such diseases as hypertension, angina pectoris, bronchial asthma, and the whole range of cardiac disease. The theory of the breaking of the barrier explained what they had been accustomed to speak of as the establishment of a pernicious tissue habit. Clinicians had also long recognized the influence of the emotions in the treatment of disease. The emotions were closely related to the progress of convalescence and to the cure of cardiac and renal diseases particularly, and treatment in various sanatoriums for this type of disease was largely based on this physiological fact. The clinician was no longer afraid to say that an uncontrollable temper, or protracted worry, might bring on a chronic interstitial nephritis. Now that there was an explanation of how emotion might produce disease, the prevention of the development of many diseases and even their cure should be better understood, and proper attention to this important phase should result.

Dr. Walter Timme believed that emotional complexes had as reactions disturbances of the normal state in the three nervous levels, the psychic, the sensorimotor, and the vegetative. As the vegetative level combined both the sympathetic and the extended vagus systems, and as these were interactive, it was hardly possible to consider one without the other. Emotions such as anger stimulated the sympathetic, but such emotions as depression, chagrin, or worry stimulated the vagus and produced physiological changes which were constantly seen; notably, visceroptosis.

One possible objection to Doctor Cannon's conclusions regarding the effect of the increased adrenaline in the adrenal veins of an animal that had been frightened, was that these same veins depleted the adrenal cortex as well as the medulla. The adrenal cortex in human beings comprised almost nine tenths of the gland, while the medulla, which produced the adrenaline, was only one tenth. In animals, the cortex was smaller proportionately than in human beings and in acerebrate humans and idiots the cortex was almost entirely absent. It was noteworthy that with such absence the individual had much less inhibition of his emotional discharges in anger and fright. It might therefore be presumed that the cortex secreted a substance which was possibly antagonistic to adrenaline and whose activity must be taken into account in such experiments as Doctor Cannon had described.

An interesting problem was propounded in considering the mutual relations of adrenaline and the sympathetic system: namely, that they were mutually stimulating; that is, adrenaline irritated the sympathetic system, which in turn stimulated the adrenal gland to a further production of adrenaline. This newly formed adrenaline again affected the sympathetic with the secondary effect upon the adrenals, and so on *ad infinitum*. Yet this was not so in fact, for it seemed that the adrenaline was immune to the sympathetic stimulation produced by adrenaline.

Dr. John Rogers recalled that only a few years ago, the ductless glands and the sympathetic nervous system were regarded as unimportant structures, but now a complete knowledge of their physiology apparently promised the solution of many of the most puzzling problems of the practitioner. Until recently, the autonomic and sympathetic nervous systems were unnamed and almost unknown; now these two groups of nerves were recognized as conveying impulses which were, in effect, opposite. The autonomic fibres in general were motor and secretory; the sympathetic, on the other hand, seemed to inhibit these motor and secretory influences. The product of the adrenal gland, epinephrine, acted upon the terminal filaments of the sympathetic and intensified its influence, or that of inhibition. The product of the pituitary or, more strictly, of the pars intermedia of the pituitary, seemed also to have some similar influence. A few recently published experiments suggested that the products of all the other endocrinous glands had some corresponding activating effect upon the terminal filaments of the autonomic group. As every important organ in the body was supplied by both autonomic and sympathetic nerves, an excess of some endocrinous secretion other than the adrenal or pituitary should increase or activate the motor or secretory impulses of the autonomic group; an excess of epinephrine, by its activation of the sympathetic, should inhibit any excessive amount of secretion which might arise through stimulation of the vagus by one or more other glands. An autonomic balance seemed to be furnished in this mechanism by the supposed vagus supply of the adrenal gland; if this was interrupted, it then became possible to imagine the origin of the disturbances now represented by the manifestations of vagotonic or sympatheticotonic conditions. Doctor Timme had hinted that adrenaline might not be the active principle of the adrenal gland; if this suspicion proved true—that is, if adrenaline was only the stable part of some labile secretion, it might be possible some day to demonstrate the mechanism of the complicated diseases of which the most common was exophthalmic goitre.

Dr. Samuel J. Meltzer wished to assure Doctor Dana that Doctor Cannon's laboratory possessed a humanizing influence and was dominated by the clinical spirit of no less a person than Doctor Cannon himself. It had been most instructive and enjoyable to hear such closely packed facts as were contained in the address, all being the result of his own observations. He offered facts, and when he offered theories they fitted tightly with his facts. Doctor Cannon's experiments pointed to the effect of the adrenals on the emotions of fear and hatred, but there was a further field for experiment in the discovery of the source of the softer emotions, such as the love of mothers for their children.

Book Reviews

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

The Newer Physiology in Surgical and General Practice. By A. Rendle Short, M.D., B.S., B.Sc. (Lond.), F.R.C.S. (Eng.), Hunterian Professor, Royal College of Surgeons; Examiner in Physiology for the F.R.C.S.; Hon Assistant Surgeon, Bristol Royal Infirmary; Senior Demonstrator of Physiology, University of Bristol. Third Edition. Revised and Enlarged. New York: William Wood & Co., 1915. Pp. xi-256. (Price, $2.25.)

Intended for the general practitioner, consulting surgeon, and candidate for examinations in advanced physiology, this little work deals with recent advances made in the study of surgical shock; the functions of the genital glands; the vitamines and their relations to beriberi, scurvy, and rickets; the growth, regeneration, and transplantation of bone tissue; the thyroid, parathyroid, pituitary, and pineal glands; the physiology of digestion and absorption; hemophilia; uric acid, calcium oxalate, and cystin in the urine; acidosis and diabetes; chloroform poisoning; the results of nerve injuries; the surgical physiology of the spinal cord, and cerebral localization. In this, the third edition, about one half the text is new, several chapters having been added and large previously included sections omitted to make room for them. Only the conclusions of the best known investigators are presented, though it cannot be said that unconfirmed theories are entirely excluded, no less than four theories as to the cause of surgical shock being set forth and compared. Some experiments performed by the author himself in relation to various physiological and therapeutic problems are set forth. In the last chapter he describes such experiments as the action of anesthetics on the skin, and concludes that such drugs as opium, belladonna, aconite, and phenol possess no true local pain relieving power when applied to the unbroken skin. The book may be warmly recommended as a summary of recently acquired physiological knowledge having clinical bearings.

The Healthy Girl. By Mrs. Joseph Cunning, M.B. (London), Hon. Med. Director to the Open-Air School in the London Botanical Gardens, and A. Campbell, B.A., Lecturer in Biology and Hygiene, Technical Institution, Swindon. London: Henry Frowde (Oxford University Press); Hodder & Stoughton, 1916. Pp. x-191. (Price, $1.75.)

This little volume supplies the need for a comprehensive yet simple discussion of health measures for the young, and is devoted especially to the young girl. The treatment is simple enough for the girl herself to follow. The special value of this book, however, seems to be as a guide for teachers and parents in the teaching of personal and sex hygiene, as well as to help them recognize such physical and nervous conditions as are now quite well understood to impede the mental progress of the pupil. In teaching the young the book tells what to say, but particularly how to say it in order that the full import of the precept shall not be lost, and yet that there shall be no offense to the sensibilities of the young.

There is just enough anatomy and physiology in the health precepts, in language that must be understood by every one. The care of the different parts of the body is taken up in order. Cleanliness, both of mind and of body, exercise, work, rest, etc., are treated at length. The chapter on menstruation, sex hygiene, and the elucidation of the problem of reproduction is particularly good, because it goes into the subject clearly, yet without offending sensibilities; the analogies drawn from plant life, to animal life, and then to human life are so gradually set forth that the child gets the proper ideals in this matter. The commoner infectious diseases receive a little discussion, which is helpful for intelligent orientation on this subject. A list of drugs for the medicine chest is a valuable aid for the boarding school.

Finally there is a comprehensive discussion of school hygiene and its effect on the health and ability of the pupil, with paragraphs illustrating the effect of overwork and poor school surroundings on height and weight, as well as the results of the open air schools.

Diseases of Children. By Edwin E. Graham, A.B., M.D., Professor of Diseases of Children in the Jefferson Medical College; Pediatrist to the Jefferson Medical College Hospital and to the Philadelphia General Hospital, Philadelphia, etc. Illustrated with 89 Engravings and 4 Plates. Philadelphia and New York: Lea & Febiger, 1916. Pp. xx-902.

This textbook constitutes a real addition to the armamentarium of the physician or of the student. While it is not so profuse in its details as some of the larger works on the subject, it yields them nothing in the matter of completeness. Indeed, the new and added features of this book quite overcome lack of detail, beside filling a much felt want. The most modern views are briefly discussed. An attempt is to present typical cases without burdening the text with unconfirmed theories, many exceptions, or variations. While not profuse in photographic illustrations, the latter are ample for this work, and there are a number of good graphic illustrations, helpful in bringing into focus a large mass of facts not possible with other illustrations.

More space is allotted to symptoms, diagnosis, and treatment than to pathology, etiology, etc. To the busy practitioner the former are after all the important elements. The chapters on infant mortality, heredity, environment, puberty, etc., are new features of the book, especially in the manner of their presentation. There is considerable space devoted to clinical methods of examination of the child, its care, infant feeding, dentition, fresh air, and exercise. The normal development of the child is taken up and complete anthropometric tables and charts are given. The important acute diseases, including infantile paralysis, are treated in detail. The chapter on nervous diseases is complete. The book is a ready reference book for the busy practitioner where no important facts are taken for granted.

Diagnostics and Treatment of Tropical Diseases. By E. R. Stitt, A.B., Ph.G., M.D., Medical Director, U. S. Navy; Graduate, London School of Tropical Medicine; Head of Department of Tropical Medicine, U. S. Naval Medical School, etc. With 86 Illustrations. Philadelphia: P. Blakiston's Son & Co. Pp. xi-421. (Price, $2.00.)

Comparing the prevailing methods of clinical study and instruction in tropical diseases with those practised in diseases of temperate climes, Stitt observed a striking tendency to base the diagnosis of the former group of affections on laboratory data alone, the bedside findings playing merely a subsidiary part and being taken as a control on the laboratory diagnosis. The present work was designed to teach tropical medicine from the clinical rather than the laboratory standpoint, though for the sake of completeness, a paragraph on laboratory methods is given under each disease heading. Discussion of the general symptomatology of each disorder is followed by a section dealing with the symptoms in detail, in which the manifestations referable, respectively, to the circulatory, respiratory, digestive, nervous, and other systems are described in turn. Special attention is also given to epidemiology and prophylaxis. One of the chief distinguishing features of the work, however, is Part II. in which a general analysis of the symptoms of tropical affections is presented, constituting, in a sense, a key to the significance of certain symptoms in the differential diagnosis of the various diseases. A general description of laboratory procedures in the examination of the blood, urine, and feces is also presented in this part. On the whole, the facts are thus presented in a manner so cross referenced that the student of tropical affections has the subject put before him from various angles—a valuable feature in the study of any branch of medicine or science in general. The text will be found eminently clear and concise. The inclusion of such conditions as malaria, black water fever, amebic and bacillary dysentery, liver abscess, pellagra, and hookworm disease render the work of value not only to the special student of tropical diseases, but to all practitioners in certain sections of the United States. Small type sections on the history and geographical distribution of the various diseases taken up are presented.

Beauty a Duty. The Art of Keeping Young. By SUSANNA COCROFT, Author of What to Eat and When; Personal Hygiene; The Reading of Character Through Bodily Expression, etc. Chicago and New York: Rand, McNally & Co., 1915. Pp. 384. (Price, $2.)

The women of America are always interested in the publications of Miss Cocroft. They have been familiar with her essays on What to Eat and When, Personal Hygiene, and the Reading of Character Through Bodily Expression. Now when she presents a book inculcating beauty as a duty or the art of keeping young, it will be read eagerly and by many. While not being technical in style, the book deals interestingly with technical subjects relating to the care of the body. Should all women become Miss Cocroft's ardent disciples, we might properly look to the development of a wonderfully perfect race.

A Manual of Fire Prevention and Fire Protection for Hospitals. By OTTO R. EICHEL, M. D., Director, Division of Sanitary Supervisors, New York State Department of Health. New York: John Wiley & Sons, Inc.; London: Chapman & Hall, Ltd., 1916. Pp. v-69. (Price, $1.)

This little volume presents in concise form the essentials to be observed in the construction, and more especially the equipment of hospitals, as necessary for the prevention of fire and protection against it. The material is drawn from the author's wide personal experience and from the recommendations of such bodies as the National Board of Fire Underwriters, the National Fire Protection Association, etc. The statements are authoritative and the recommendations are wise, simple, and can be followed easily. The book is altogether commendable and will be of material service to hospital superintendents and to others engaged in the management or construction of hospitals.

Interclinical Notes

A writer in the *Smart Set* for November names his heroine Fleurette Lamont; she is supposed to be a Frenchwoman. Lamont, however, is not a possible French name; we could have Lemont or Lamontagne, but not Lamont, which, curiously enough, is pure Lowland Scotch.

* * *

Some idea of the delightful temperature of a British dwelling may be gathered from an advertisement in an English magazine for November, which sets forth the advantages of having a billiard table in the home. Among the specifications of the table are "frost proof rubber cushions."

* * *

Not long since we recorded with regret the demise of the American edition of the *Strand Magazine*. The English edition, however, still recalls the green bay tree. One of the best things in the November issue is the story by our distinguished colleague, Sir Conan Doyle, of the great European War. The British Campaign in France, with its spirited illustrations, is a masterpiece of descriptive writing, and we are astonished that no American periodical seems to have had the enterprise to reproduce it.

* * *

Montreal, Canada, seems to be undergoing a poliomyelitis scare quite similar to the one experienced by New York a few weeks ago. Cases seem to be very few in number—as a matter of fact they numbered six on October 21st—but schools, moving picture houses, etc., have been closed, domestic pets have been impounded, and terrifying articles have appeared in the daily papers, so that all is ready for a first class panic.

* * *

A lady with a four year old child was put off a Montreal train from New York a few days ago, because she was not provided with a physician's certificate of some kind concerning the child. Ignorance of the law, as usual, proved to be of no avail in her case, and the inspector on the train acted as he was obliged to. The mysterious part of the affair is why the agent who sold this woman two tickets for a quarantined city made no mention of the certificate that would be required. Had he done so, there would have been no trouble in procuring the document, and the two passengers would not have been put off at a desolate country station, bewildered and frightened by the first news they had received of the presence of a dangerous disease at their destination. From the days of yellow fever until now the presence of epidemics has seemed to have the faculty to annihilate all brain power among officials. The supposed precautions we used to take against yellow fever, backed up as they were by guns, were quite futile, and it is about ten to one that we are doing exactly the wrong thing about poliomyelitis.

* * *

The necessity for immediate assistance to the maimed soldier is a subject of comment in the *Review of Reviews* for October; that journal summarizes an article by Signor Angelo Ragghianti and Signor Salvatore Dalmazzoni in a recent issue of *Rassegna nazionale:* The wonderful improvements that have been made in the construction of artificial limbs, rendering it possible to communicate to them a number of special movements by using the motor power still existing in the stump left after amputation, have opened up spheres of activity for the maimed heretofore considered as permanently closed to them. By patient training on the part of competent instructors, and by the exercise of the necessary will power on the part of the pupils, an artificial arm can be made to do much of the work that the natural arm could do; more slowly, of course, and not quite as skilfully, but still sufficiently well to render the maimed man a useful member of society, one who can still have a share in the productive work of the nation. The professional reeducation should be conducted earnestly and wisely, always following the general principle of keeping the man in touch with his native region and with the vocation he formerly pursued. Hence, all foolish sentimentality should be rigidly banished. Above all the men should not be taught any futile occupation, depending for its success only upon the pity and charity of those who may be induced to buy the things manufactured. It can be made possible for each of these victims to earn something in a proper and legitimate way, and he need not have recourse to one that would make him, in some sense, an object of charity. Another important thing is to avoid teaching an undue number the few more easily acquired arts, such as typewriting, photography, telegraphy, telephony, etc. This would tend to disorganize the necessary distribution of labor in the land, with the consequent lowering of wages and the risk of unemployment.

* * *

"Kathleen Parlow is the peer of all women violinists," according to one rhapsodizing advertisement writer. How astonished that writer and many who agree with him are going to be if they look up the word, peer, in a dictionary. The foregoing use of it is grotesque, and makes the sentence express exactly the opposite of what the writer was trying to say.

Meetings of Local Medical Societies

MONDAY, *October 30th.*—Poughkeepsie Academy of Medicine (annual).

WEDNESDAY, *November 1st.*—Brooklyn Society for Neurology; Society of Alumni of Bellevue Hospital; Harlem Medical Association; Bronx Medical Association; Elmira Academy of Medicine; Psychiatrical Society of New York; Society of Alumni of St. John's Hospital, Brooklyn; Schenectady Academy of Medicine.

THURSDAY, *November 2nd.*—New York Academy of Medicine (stated meeting); Brooklyn Surgical Society; Practitioners' Club, Buffalo; Geneva Medical Society; Glens Falls Medical and Surgical Society.

FRIDAY, *November 3rd.*—New York Academy of Medicine (Section in Surgery); New Utrecht Medical Society; New York Microscopical Society; Gynecological Society, Brooklyn (annual); Practitioners' Society of New York; Corning Medical Association.

SATURDAY, *November 4th.*—Benjamin Rush Medical Society, New York.

Official News

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers of the United States Public Health Service for the seven days ending October 18, 1916:

Applewhite, C. C., Acting Assistant Epidemiologist. Directed to proceed to Jasper, Ala., for resurvey of sanitary conditions.

Applewhite, J. D., Field Investigator. Directed to proceed to Jasper, Ala., for resurvey of sanitary conditions.

Baughman, D. S., Assistant Surgeon. Relieved from duty at the San Francisco Marine Hospital, and ordered to proceed to San Francisco Quarantine Station, Angel Island, Cal.

Boggess, J. S., Surgeon. Relieved from duty at Seattle, Wash., and ordered to proceed to San Diego, Cal., Quarantine Station and assume temporary charge.

Collins, G. L., Surgeon. Granted one day's leave of absence en route to station at Washington, D. C.

Foster, M. H., Surgeon. Granted twelve days' leave of absence from October 10, 1916.

Harrington, F. E., Assistant Epidemiologist. Directed to proceed to Jasper, Ala., for resurvey of sanitary conditions.

Kalloch, P. C., Senior Surgeon. Granted three days' leave of absence from October 17, 1916.

Kempf, G. A., Passed Assistant Surgeon. Directed to report to Surgeon T. Clark at Mineola, L. I., for survey of children in connection with school hygiene.

Lumsden, L. L., Surgeon. Directed to attend the meeting of the American Public Health Association at Cincinnati, Ohio, October 24-27, 1916.

Parran, Thomas, Field Investigator. Directed to proceed to Jasper, Ala., for resurvey of sanitary conditions.

Reuter, R. A., Field Investigator. Directed to proceed to Jasper, Ala., for resurvey of sanitary conditions.

Robinson, D. E., Surgeon. Relieved from duty at Rockland, Me., and directed to return to station at Ellis Island, N. Y.; ordered to represent the Service at the Third North Atlantic Tuberculosis Conference at Newark, N. J., October 20-21, 1916.

Rucker, W. C., Assistant Surgeon. Directed to attend the meeting of the American Public Health Association at Cincinnati, Ohio, October 24-27, 1916.

Schwartz, L., Passed Assistant Surgeon. Granted one month's leave of absence from October 16, 1916.

Sharp, W. K., Field Investigator. Directed to proceed to Jasper, Ala., for resurvey of sanitary conditions.

Smith, L. H., Assistant Surgeon. Relieved on Coast Guard cutter *Onondaga*, and ordered to report for duty on Coast Guard cutter *Yamacraw*.

Sweeney, A. R., Assistant Surgeon. Granted fourteen days' leave of absence from November 6, 1916.

Trask, J. W., Assistant Surgeon. En route under orders October 7, 1916, and directed to visit Clay County, Mo., to inspect studies of rural sanitation.

Treadway, W. L., Assistant Surgeon. Directed to proceed to Mineola, L. I., when directed by Surgeon T. Clark, for duty in survey of children in connection with school hygiene.

Warren, B. S., Surgeon. Directed to visit certain industrial institutions in connection with studies of health insurance.

Weldon, L. O., Assistant Surgeon. Directed to report to Surgeon T. Clark at Mineola, L. I., for survey of children in connection with school hygiene.

Wildman, H. V., Jr., Assistant Surgeon. Directed to report to Surgeon T. Clark at Mineola, L. I., for survey of children in connection with school hygiene.

Woods, E. O., Assistant Surgeon. Relieved from duty at Seattle, Wash., and ordered to report to Coast Guard cutter *Unalga* for duty.

Young, G. B., Surgeon. Directed to report at Bureau for conference relative to investigations of health organization and administration in Minnesota.

Births, Marriages, and Deaths

Married.

Brown-Aldrich.—In Malden, Mass., on Saturday, October 7th, Dr. Ralph N. Brown and Miss Helen M. Aldrich.

Giguere-Davis.—In Lowell, Mass., on Saturday, September 30th, Dr. Alfred J. Giguere and Miss Madeline E. Davis.

Hawes-Porter.—In Lynn, Mass., on Wednesday, October 4th, Dr. Alfred Taylor Hawes and Miss Anna G. Porter.

Johnson-Hager.—In Clinton, Mass., on Wednesday, October 11th, Dr. Allan C. Johnson and Miss Mary Alice Hager.

King-Hudner.—In Fall River, Mass., on Tuesday, October 10th, Dr. George Clifford King and Miss Mary E. Hudner.

LaFrance-Dion.—In New Bedford, Mass., on Thursday, October 12th, Dr. Arthur D. LaFrance and Miss Marie A. Dion.

LaGasa-Perry.—In Tacoma, Wash., on Thursday, October 12th, Dr. James LaGasa and Miss Lillian Perry.

Mathews-Sullivan.—In Providence, R. I., on Tuesday, October 10th, Dr. Frank H. Mathews and Miss Elizabeth H. Sullivan.

Munger-Pattee.—In Manchester, N. H., on Wednesday, October 4th, Dr. Ray Thomas Munger, of Fanwood, N. J., and Miss Grace Elizabeth Pattee.

O'Rourke-Sparks.—In Dorchester, Mass., on Sunday, October 8th, Dr. Edward J. O'Rourke, of North Cambridge, and Miss Frances R. Sparks.

Died.

Ferguson.—In Baltimore, Md., on Wednesday, October 11th, Dr. Frank C. Ferguson, aged thirty-seven years.

Graves.—In Saco, Me., on Wednesday, October 11th, Dr. Stockbridge P. Graves, aged ninety years.

Hersh.—In McComb, Ohio, on Monday, October 2nd, Dr. Edward G. Hersh, aged fifty-one years.

Kennedy.—In Washington, D. C., on Friday, October 6th, Dr. James S. Kennedy, Major, United States Army, aged fifty-eight years.

Kyle.—In Philadelphia, on Monday, October 23rd, Dr. D. Braden Kyle, aged sixty-three years.

Lees.—In Bridgeport, Pa., on Monday, October 9th, Dr. John S. Lees, aged seventy-six years.

Lesser.—In Brooklyn, N. Y., on Monday, October 23rd, Dr. George Lesser, aged forty-six years.

Lincoln.—In Boston, Mass., on Tuesday, October 17th, Dr. David F. Lincoln, aged seventy-five years.

McKay.—In San Diego, Cal., on Saturday, September 30th, Dr. Winfield W. McKay, of Hailey, Idaho, aged sixty-nine years.

McKenna.—In Long Island City, N. Y., on Tuesday, October 17th, Dr. Henry J. McKenna, aged thirty-five years.

McKibben.—In Amaranth, Pa., on Friday, October 13th, Dr. William L. McKibben, aged seventy-six years.

Mangan.—In Rutland, Vt., on Saturday, October 7th, Dr. Matthew J. Mangan, aged forty-five years.

Mason.—In Suisun City, Cal., on Thursday, October 5th, Dr. D. N. Mason, aged seventy-three years.

Matson.—In Brooklyn, N. Y., on Sunday, October 15th, Dr. Nathaniel Matson, aged seventy-seven years.

Michael.—In Dayton, Ohio, on Sunday, October 8th, Dr. Francis M. Michael, aged sixty-six years.

Morton.—In Philadelphia, Pa., on Thursday, October 12th, Dr. Thomas J. Morton, aged fifty-four years.

Rose.—In Harvey, Ill., on Wednesday, October 11th, Dr. Marie F. Rose.

Stackhouse.—In Moorestown, N. J., on Friday, October 6th, Dr. Asa M. Stackhouse, aged seventy-two years.

Tiffany.—In Mount Custis, Accomac County, Va., on Monday, October 23rd, Dr. Louis McLane Tiffany, of Baltimore, aged seventy-two years.

Weaver.—In Dayton, Ohio, on Saturday, October 14th, Dr. Fred C. Weaver, aged forty-six years.

Webfr.—In Louisville, Ky., on Friday, October 6th, Dr. Harry C. Weber, aged forty-six years.

Welsh.—In Shreveport, La., on Saturday, October 7th, Dr. Emmet Alvin Welsh, aged fifty-two years.

White.—In Tarrytown, N. Y., on Thursday, October 12th, Dr. William H. White, aged eighty-four years.

AND THE PATIENT IS LEFT OUT.*

BY ROBERT T. MORRIS, M. D., F. A. C. S.

New York.

You know the schoolboy's rule in grammar, "Never use a preposition to end a sentence with." According to a somewhat similar rule the title of my paper has been constructed.

In the midst of our rapidly advancing concentration upon special studies, does a given physician today really care to know what is the matter with a patient, or does he much prefer to find something in which he is specially interested? Let us take, for example, a concrete case of diabetes mellitus. Is the physician to assume the responsibility of treating that patient along lines of his pet dietary régime? Diabetes mellitus is nothing but a symptom, like a cough or a sneeze. Should the physician be content to make a diagnosis of the symptoms, and consider that to represent a diagnostic entity? No! With the symptom of diabetes mellitus making a sign to him, beckoning him on, the physician is to proceed to find out what really does ail the patient. Some of us know that diabetes mellitus is always due to hyperglycemia. Some of us know that hyperglycemia in a given case may be secondary to some peripheral irritation or to some focal infection which is exciting the adrenal glands, and these in turn are whipping up the thyroid gland, the whole chromaffin system, and the liver—a whole series of disturbances of function manifested in one salient symptom which happens to attract the doctor's attention because of its easy evidence.

When taking up the several forms of diabetes mellitus from a therapeutic standpoint, we are to begin with the question of what peripheral irritation or what focal infection may be driving the adrenals overtime. The physician who does not go at a case in that sort of way is a superficial practitioner, interested only in his direct treatment for the symptom, and the patient as a whole is left out.

Who's to blame? Well, perhaps we cannot call it blame! With our rapid advance in laboratory methods and in the correlation of special knowledge, one man scarcely knows what another man is about. What chemist knows much about the work of another chemist in another field of the subject? Where is the geologist today who can write a textbook covering the whole subject of geology? The day is past when that sort of thing was possible. Our laboratory advances have been almost explosive along lines of special study, and by way of the laboratory we may find something in which we are interested and which we set out to find, in almost any man in this room. If I send a patient to the office of a heart specialist, and if the patient returns without heart disease, it is because the doctor was not in. The field of neurology has become so elaborated by physicians and metaphysicians, that we are in luck if we can obtain two agreeing opinions from two different neurologists to whom we send our unhappy patient.

What are the layman's chances for getting into the right hands when choosing a consultant? You all assume a very thoughtful look when *I* ask that question. A layman trying to select a competent medical adviser today is very much like a client in a court of law trying his own case. It is true that many people have the sort of confidence in the doctor that they have in the clergyman, and both professional men at the same moment are perhaps taking the trusting person in one direction straight toward Heaven.

Tomorrow the layman is to depend upon a new kind of consultant, in cases of chronic illness at any rate. This new kind of consultant will not depend upon his own knowledge and wisdom, except to the extent required for getting together a group of facts from a number of authorities, that bear upon the case which he has in mind. That will be skilled labor, requiring the best type of synthetic and judicial faculty. The consultant's work and his opinion will be somewhat expensive, but the good old days are no more, when a man could suffer and die cheaply. A few consultants have already made a grouping of experts and of laboratory facilities in such a way that the cost may be reduced to moderate terms for the clerk whose income is twelve hundred dollars a year and whose expenses are eleven hundred and sixty dollars. The consultant of tomorrow is to be a man who is not overimpressed by the new ideas of enthusiasts, yet he will avoid the skepticism which overlooks the basic truth in almost every new movement—otherwise he will be a prejudiced adviser and the patient will be left out. When the ideas of Lane relating to colonic infections were presented, we soon came

*President's address at the meeting of the American Therapeutic Society, Detroit, June 9, 1916.

to know that Lane had struck a line of cleavage into a great truth, but his immediate conclusions were repellent to conservative doctors, some of whom stepped backward and out of date in response. It remains for the consultant of tomorrow to learn that something is behind the colon, and to discover the significance of that something in cases which surgeons of the Lane school would subject to operative procedure as ignorantly as the internist treats a case of diabetes, and leaves the patient out.

The oral surgeon with a neurasthenic patient finds by way of the laboratory that apical infection of a tooth root is in evidence. He determines the presence of Streptococcus viridans. He knows that various rheumatisms may be caused by that streptococcus. He knows that endocarditis may be caused by that streptococcus. He knows what Rosenow has recently told us about appendicitis, cholecystitis, and gastric ulcer being caused by the action of that streptococcus. Knowing all this, the oral surgeon is proud in his belief that he has discovered a basic feature in the ill health of his patient, yet the case may not really belong to him at all. The throat specialist finds infected tonsils in this same patient. He goes to the laboratory and raises a fine colony of Streptococcus hæmolyticus. Almost everybody knows what dreadful things are done by the toxins of that particular streptococcus at times. Removal of the tonsils is advised, yet the case is not studied as a whole, and the patient is left out. If an opthalmologist is consulted, he very likely will find our patient suffering from the effects of eye muscle imbalance, with irritation of basal centres of the brain and consequent disturbance of the automatic and sympathetic nervous systems. The ophthalmologist believes that the case has belonged to him all along, and he is impatient with the men who had overlooked the eye muscle feature, yet it may be that the internal rectus muscles in the case are showing selective affinity for toxins or waste products from a distance. Somebody tells the patient to consult a surgeon, who finds a rattling bolt in the works in the form of a loose kidney. The surgeon perhaps believes that the case belongs to him, and that the moving kidney is a source of peripheral irritation, which explains the neurasthenia, but the patient as a whole is left out. A loose kidney is a very important thing in cases in which it is important, and it is the business of various doctors to get together and determine the exact status of that feature in any given case. The psychanalyst, taking into account the psychic phenomena of our neurasthenic patient, finds that the physical trouble is due to a mental conflict between repressed impulses, but the patient as a whole is left out.

An expert interested in our new problems of acidosis discovers that the patient is not passing certain acids and byproducts over the kidney threshold properly, and he says that these dammed products (not being profane) are the cause of all the trouble. He proceeds to treat that particular symptom, and the patient is left out. The patient goes to a rest cure doctor and becomes very much improved, at an expense of so much an hour of improvement, but upon returning to real life, which is not a rest cure, finds that treatment and daily life are incompatible. The hydrotherapy institute and the dietetic sanatorium both allow our invalid to gain weight, but only while the patient waits. The osteopath and the chiropractic inform our patient that the occipital headache is caused by the atlas being out of joint, and they proceed to bestow punishment which is not deserved, while the sufferer decides to feel better in order not to lose the worth of good money expended. The diagnosis of an atlas out of joint is the only one that is always wrong, yet people are not to be blamed for turning to medical outsiders when members of the regular profession do not help them enough.

Who is to make up a brief for the neurasthenic patient? Who is to act as the lawyer acts when getting together material for final advice to a client? I see men in this audience who are competent to make briefs. Round about the country at large, and round about the world at large, may be found a small but hopefully growing number of men who know how to make up a brief relating to almost any sort of chronic illness. These are to be the consultants of tomorrow. They will take charge of the ideas, findings, beliefs, and enthusiasms of various specialists, pass the parallel rays of light through the lenses of their minds, and focus them upon the case of any one patient. For some years, I have tried to do this sort of thing, particularly in relation to questions of peripheral irritation and focal infection. The reason I took up systematic investigation in the interest of diagnosis was because so many cases sent in for surgical operation were not properly cases for operation at all. Furthermore, a good many patients were seen during the year who had been subjected to ineffective operation. The number of ptosis cases in which the appendix has been removed would make interesting pabulum for yellow journal readers. Patients with thyroid enlargement, with duodenal ulcer, and with symptomatic pelvic conditions, are subjected to operation without question beyond that of finding conditions which appear superficially to be surgical in their nature. How many patients during the year are subjected to operation for facial neuralgia, even to an operation for removal of the Gasserian ganglion, without having a single question asked about focal infection or peripheral irritation? When making elaborate diagnoses with the aid of specialists and of laboratory experts, I found that my income from surgery was cut down very seriously. In other words, the more I knew, the less money was it possible to make.

A word for the other side of the question:

> The best line ever penned by man
> Is "on the other hand."

On the other hand, then, we shall find very many cases not believed to be surgical that are really surgical in some aspect. Many of the neuroses, neurasthenias, and psychoses may be traced back to some precipitating factor, even though it may not be a causative factor, which will respond to surgery in such a way as to allow the patient to become again a well fitting unit in the social complex. The expense of going at a case fundamentally is sometimes large, and worse than that, sometimes fruit-

less. It is true that the poor patient may have the advantage of hospital and laboratory facilities, and yet he is more than likely to be admitted to some department of a hospital by the entry clerk. In that department of the hospital he is pretty certain to receive treatment by the specialists of the department only. I want five millions of dollars today for the purpose of adding to one of the teaching institutions a systematized machinery for obtaining thorough diagnosis for every patient sent in to the institution. I do not want a dollar of the amount for myself, or any salary for administering the fund, which would be forthcoming from many men for many institutions could they but know what we doctors know about opportunities for rendering service to the public.

When a patient has been sent to some one department of a hospital today, we are apt to hear a good deal of mutual recrimination between experts in special fields. The ophthalmologist asks why the question of eye strain was overlooked in a given case. The oral surgeon wishes to know why no one took a radiograph of tooth roots in a search for apical infection. Each one of several specialists asks why the patient was not sent to his department. There has been no one steering hand, no one disinterested brain to direct that hand in the interest of the patient who needs a guide, philosopher, and friend. What patient today, sent in to a public or to a private hospital, manages to have the question of allergic response to a toxin or to a waste product worked out? Yet that is one of the largest of our new problems, and one of the most essential, if we are to know why one patient suffers more than another from the same kind of illness.

I am indebted to our society for the impetus which has led me to the custom of making up a brief for almost any patient with a chronic illness. As a surgeon it was impossible to keep up to date in surgery alone. Advances in that field have become so rapid that every surgeon is out of date in some part of his work and his thinking. When attending the meetings of this society, I was obliged to listen to papers on all sorts of topics, many of them entirely out of line with my reading even, because of time limitations. As a result of getting so many perspectives upon the whole field of therapeusis, it is now fascinating work to make up a brief of a case, and I would like to begin my whole professional work all over again.

There is another side to the question which I have not mentioned, and that is the moral side. A specialist is prone to concentrate attention so closely upon whatever interests him in a case that the patient as a whole is left out. His position approaches that of the business man. The difference between a profession and a business is this: In a business you are thinking of yourself, and in a profession you are thinking of somebody else.

The specialist is to become more and more necessary, and he is to command higher and higher fees for services rendered, but he is not to be allowed to get very close to any trusting patient, and he is to be relegated to the position of therapeutic resource.

616 Madison Avenue.

IMPOTENCE IN THE MALE.

A Preliminary Report on the Use of the Anterior Lobe Pituitary Body,

By Thomas C. Stellwagen, Jr., M. D.,
Philadelphia,
Assistant Professor Genitourinary Surgery, Jefferson Medical College.

The subject of impotence, in its various forms, is one of vital interest to practitioner and patient. Impotence unfortunately is often surrendered to the quack and the charlatan. It has always seemed that a patient suffering from sexual weakness is to be pitied. It is he that makes quackery profitable. This can be explained in several ways.

1. The management of such cases is usually difficult, and the truth may do harm if told to the patient.

2. In the young man the trouble is usually preceded by masturbation or sexual excesses, and of these the patient is loath to speak; consequently we are hampered by an incorrect history.

3. The treatment is generally slow to show results and the patient becomes discouraged.

The foregoing, and other reasons that might be added, are harassing both to patient and doctor. In consequence the patient is often lured to the irregular practitioner. He consults one of these inhuman Shylocks and signs a legal form of contract that offers him no redress, pays in advance, and in due time is fleeced and left a neurasthenic. Occasionally the patient so handled becomes profoundly depressed, mutilates his genitalia, or destroys his life. Unfortunately, we find in the advertising columns of our daily papers, and among some that clamor for decency and clean journalism, the glaring statements of cure and relief from all forms of sexual weakness.

It has always been a belief with us that some of the unhappiness in life is directly due to some form of impotence or other sexual disturbance. We believe that were it possible to determine the true cause of self destruction in not a few cases of suicide, it could primarily be laid to some vegetative defect.

The use of animal extracts and portions of their carcasses as medicine is not merely a recent practice, to quote from the paper by Dr. Carey P. McCord (1). He states that in 600 B. C., portions of the testes were used in treating obesity. Swine's fat, dog's dung, fat of the serpent, hair of the virgin goat, and human bone were commonly given. Beetles, bugs, and many other insects were supposed to possess powerful therapeutic properties and were often used.

We know today that the internal secretion of the ductless glands plays a most important part in the regulation of the growth of the body. We know further that in disease of certain of these structures mental and physical defects ensue that can be explained only by the presence of such disease. We know still further that rational treatment administered with the idea of supplying the deficient internal secretion often produces marvelous results. The converse has also been proved; that excessive secretion manifests itself as disease, and when controlled by surgery or medicine effects some re-

markable cures. The entire subject of organotherapy is still in its infancy, and physiological chemists are devoting time and study that must bear fruit in the future.

The problem of sexual weakness or impotency is of great importance and one that is not well understood. There have been many methods of treatment devised and numerous drugs and combinations tried. Each has had its day and its advocates, but we believe we express the opinion of the profession when we say that most of them have been failures.

We recognize that tonics and tissue builders are often of value in restoring the tone of a depleted nervous system and often do good. We think that the sexual power in some instances is an index of the physical well being of a man. There are numerous instances to the contrary, however, that offer the exception to test the foregoing statement, notably those suffering from tuberculosis, from certain types of malignant disease, and from other isolated instances of sickness. These, however, are rare, except in tuberculosis, where the vegetative functions seem to be overstimulated.

An impotent man is not to be laughed at, or ridiculed and passed over by his physician. He is a sick man and deserves intelligent advice and treatment. The sexually deficient subject is often a drone in our social fabric; he it is that sometimes becomes the pervert, the suicide, or the madman. Ignorance, prudery, and a false sense of propriety often make light of such patients and they are condemned to lives of mental misery aggravated by the consciousness that they are lacking in the power of procreation. This one fact more than any other should have a far reaching influence upon the conduct of such a case.

A urologist's advice is so often sought by these patients that it seemed to us that a report embodying the results obtained in six cases would not be amiss. The preparation that has proved of most value in our hands is one of the anterior lobe of the pituitary body.

Case I. Man, forty-three years of age. Family history negative, except for one tuberculous ancestor. Previous history: Had had the usual diseases of childhood and an attack of typhoid fever at the age of twenty-two years, from which he made an uneventful recovery. No venereal history. The patient had masturbated once or twice weekly up to the age of twenty years, when he ceased the practice. Following the cessation of masturbation he had nocturnal pollutions that never worried him. For these he did nothing, and they stopped after his marriage, which occurred at the age of twenty-six years. He was able to have successful intercourse with his wife, as attested by the birth of three normal children. He had intercourse about twice weekly and had not made it a practice to attempt a repetition of the act during the same night. His erections were normal, his desire was normal, intromission was accomplished without trouble, and the seminal discharge was apparently of normal consistence, odor, color, and amount.

About four years ago, he assumed a business of his own and gave much time and mental energy to its organization and conduct, frequently working until a late hour. About a year after his new business began, he noticed that his desire for intercourse seemed to be waning. Following the lack of desire, when he had an erection it was not a strong one. The head of the penis remained soft. At times desire would be normal and he would feel a sense of well being, but he was now unable to get a perfect erection and the few times that he was able to have intercourse he had a premature emission of a very thin, watery fluid.

The treatment of this case had been undertaken by several different physicians, who had used tonics, general massage, hydrotherapy, electricity, and rest in the woods, but all to no avail. He presented himself a much dejected man, and stated that he did not wish any more children, but that he would like to feel that he was still able to procreate. His state of mental unrest was largely due to the fact that he had utterly failed in recent attempts at intercourse.

We put him upon a three months' treatment, explaining that during that time he must sleep apart from his wife and dismiss the sexual idea from his mind. This he agreed to attempt to do and did. He received a five grain tablet of anterior lobe pituitary body, three times a day, after meals, and came to the office twice weekly for a prostatic massage. The diet was not altered, nor was his daily routine. At the end of one month he noticed no change and became despondent, but we advised him to have patience and explained that we did not look for improvement until the end of about two or three months. During the middle of the third month, desire began to return and with it erections which, as he stated, were better. At this time he had three emissions. At the end of the three months he was permitted to attempt intercourse, which was accomplished successfully.

This patient, after one year, has shown every evidence of a permanent cure and at present is thoroughly competent sexually, while his general health is apparently perfect.

Case II. Man, fifty-four years old, widower, well developed and well nourished subject, had been a widower for past five years. His wife died from tuberculosis after a lingering illness, in consequence of which he had not had intercourse for three years previous to her decease. He was the father of two healthy children and wished to marry a woman thirty-two years of age, but knew he was unable to perform the sexual act. Upon questioning he said that he had attempted intercourse with women of easy virtue, having tried both blonds and brunettes, but to no avail; consequently he felt incompetent. When questioned as to erotic sensations when in company with his fiancée, he stated that they did not exist.

This patient was placed upon a course of treatment similar to that in Case I and at the end of four and one half months was apparently normal for a man of his years. He married and has since been able to conform to his sexual duties. At present he believes his wife to be pregnant. To this patient we explained that sexual excitement without gratification was most pernicious for him and accordingly he was instructed to see his fiancée only once a week and then very formally.

It may be well here to emphasize what we believe to be a fact, namely, that impotence and other forms of sexual weakness, including physical defects such as varicocele, painful testicles, neuralgia of the cord, and in some rarely possible instances, hydrocele, are at times either produced or at least much aggravated by sexual excitement without subsequent orgasm. We know no more pernicious practice than the ardent love making of the young suitor over a long period of time. We believe that many cases of obscure nervous affections, sexual degeneracy, or weakness may be traced to some such cause. In short, we insult nature by such practices, and after a while she gives up and im-

potence results from exhaustion of the spinal genital centre. What could be a practice more dangerous to the sexual powers than withdrawal before emission? This practice is apparently common among the Hebrew race, especially among the younger men and in our opinion it accounts for much of the sexual weakness among them.

Case III. Man, aged thirty-five years, married five years, had no children. He had the usual diseases of childhood and an infection by the gonococcus at the age of twenty-six years, of which he was apparently cured. Prostatic secretion showed eight leucocytes to a field. Urine report negative. Present trouble: About five years ago, desire became intense and he found it necessary to have sexual intercourse once or twice each night. This lasted for about six months. Desire then suddenly ceased and since that time erections have been but a memory.

At the time of the excessive sexual desire, he had considerable burning and stinging along the urethra when he urinated. The receptacle in the morning, he stated, was coated at times by a reddish and then again by a very light yellow sand. At this time he was spending his vacation upon a farm and had eaten a great amount of fruit and tomatoes. He would frequently eat them while in the fields. In our opinion he probably had uric acid and calcium oxalate showers, due to the inordinate consumption of fruit and tomatoes. These showers, through irritation of the genitourinary mucous membrane, excited the spinal centre—hence the eroticism.

This patient had his diet regulated, eliminating excesses of starches, sugars, and fats. A diet should be carefully selected with the idea in mind to give sufficient calories to do the day's work and have a surplus from which to build up a reserve. He was told to live apart from his wife for four months, to take cold sponge baths, and was put upon a two and one half grain tablet of anterior lobe pituitary body three times daily after meals. This man did not have prostatic massage. At present his sexual powers are apparently normal.

Case IV. Man, aged fifty-eight years, well nourished, strong, and apparently healthy; unmarried; had the usual diseases of childhood; pneumonia at thirty-eight years of age, from which he made an uneventful recovery. Had had four attacks of gonorrhea and a chancre ten years ago. Wassermann negative, gonococci negative, prostatic secretion apparently normal. His semen contained nonmotile spermatozooa. Hemoglobin, sixty-five per cent. Present trouble: He had had a mistress for the past nine years, but for two years had been unable to have successful intercourse. Has had emissions while the penis was in a flaccid state. This man's mistress stated that his sexual power at one time was very great and that during that period he drew upon it to excess. This period of unusual sexual excitement followed closely upon his syphilitic infection and might have been induced by some cord irritation.

This case was treated as follows: Citrate of iron by hypodermic injection one grain, every third day, for seven injections raised his hemoglobin from sixty-five to ninety per cent. He was then put upon Basham's mixture and strychnine three times daily. He was kept upon this line of treatment for two months. He was then placed upon the anterior lobe pituitary body grains five, three times a day, after meals, with massage of the prostate and the passing of a Beniqué curved bougie twice weekly. The bougie was permitted to remain for eight minutes. After dilating up to No. 32 French, the bougie was discontinued. The prostatic massage was continued for four months.

At the end of the third month he felt better, looked improved, and began to have the usual morning erections consequent upon a full bladder. This gave him heart, and with a return of confidence he had successful intercourse and since then has been able to have connection about every ten days.

Case V. Man, aged sixty-two years, single; well nourished, except that he had recently lost ten pounds in weight. Blood pressure, 149; hemoglobin, 92. Urine negative. Prostatic secretion, twenty two leucocytes in the field. Heart lacking in muscular tone and snap. We could not determine any lesion, but his physician, for whose opinion we had great respect, said he had a slight mitral regurgitant murmur, transient in character. Patient was well nourished, but not rugged. He had very few diseases as a child and did not recall any severe illness. Had one attack of gonorrhea at twenty-three years of age, from which apparently he made a complete recovery.

This patient consulted us, he said, because his sexual powers were waning. He wished to know whether any course of treatment might conserve the remainder of power that he still possessed. He was put upon prostatic massage and received five grain tablets of anterior lobe pituitary body. After about two and one half months he stated his sexual powers were much improved, and that during one visit to a woman with whom he was accustomed to have connection, he had intercourse twice in the same night. His general health was much improved and a slight dyspnea from which he had suffered passed entirely away. He plays eighteen holes of golf without great effort, which was impossible before the pituitary body was exhibited.

He complained of hyperacidity, which proved to be a temporary hyperchlorhydria. This gave him some discomfort, but passed away almost coincidently with the stopping of the tablets of pituitary body. With him it became necessary to intermit the administration of the tablets for a few days in order to prevent hyperacidity. This patient is still under observation and apparently remains sexually potent.

Case VI. Widower, aged sixty-one years, wife died eight years before. Previous history uneventful; no venereal history. Patient stated that his sexual powers had been practically negative for past three years. He had been able, however, to get a feeble erection, but could not have a successful intercourse. Blood pressure, 150; hemoglobin, eighty-five per cent.; urine negative. Prostatic secretion contained eight leucocytes in the field.

This subject was placed under treatment for four months, at the end of which time he had successful intercourse and has continued to accomplish the act once about every two or three weeks. He states that he feels much improved in general health and has not noticed any untoward symptom except a mild hyperacidity of the gastric juice.

COMMENT.

Our attention was first called to the use of pituitary body in general weakness by an observation upon a patient to whom the preparation was given in a purely empirical way. He was suffering from premature senile decay. The patient, a man aged forty-eight years, had some undefinable and unexplainable circulatory weakness for which anterior lobe pituitary body was given.

He showed decided improvement and during the course of his treatment remarked that he felt

a return of sexual desire, also that his powers of erection, which had been negative for some time, seemed to be returning. This latter fact he dwelt upon so frequently that it determined us to apply it in the treatment of such cases. We have tried the preparation in three cases of younger men suffering from sexual neurasthenia, but with no special improvement. This fact we do not attempt to explain, but we feel that in them the nervous element so predominates that it governs the situation, and that unless some means are found to put it in abeyance, all methods of treatment must fail. In short, we have tried to impress upon them that they must be philosophical in order to gain by the treatment.

No untoward symptoms have been produced by the administration of the preparation, except slight hyperacidity of the gastric juice. In other cases now under observation this hyperacidity is present, consequently it may be of use in achylia gastrica. It is our intention at a later date to offer a more complete study upon another series of cases.

The fact that prostatic massage and some other remedies were used in the treatment of the foregoing cases in a measure invalidates the testimony in favor of the anterior lobe pituitary body; nevertheless, we feel that the preparation played a very decided part in the cure of the cases. Previous to its use, the methods that were resorted to generally failed, hence our preliminary conclusion.

CHRONIC APPENDICITIS AND CHRONIC INTESTINAL TOXEMIA.*

Their Association and Differentiation,

BY G. REESE SATTERLEE, M. D.,
New York.

The subject of appendicitis may be time worn, but it needs still further study and investigation. The diagnosis is seemingly simple and the operation for its relief unusually easy. Relief from underlying conditions is often a difficult problem. The anatomy, pathology, bacteriology, and the reasons for removal of the diseased organ have been very thoroughly worked out, but there is still a wide field to be studied. There are many viewpoints as to the etiology of the condition, so there must still be room for investigation. The etiology of acute appendicitis seems to be simpler to explain than that of chronic appendicitis, although the two conditions may be closely related.

Heredity and family predisposition seem to play an important role in inflammations of this organ. As examples of this, Forcheimer (1) gives a series of observations in which a strong hereditary tendency was present, and J. W. Draper describes seven cases of appendicitis in one family. The explanation of these cases may be, some hereditary, characteristics of the intestinal tract; heredity, however, may play no part, infection from the intestine directly or through the blood stream or lymphatics, being the real cause.

We are a long way from proving hereditary characteristics in the intestinal tract, though we feel that heredity has much to do with handing down types and peculiarities of this part of the body as elsewhere. As examples of heredity, may be cited two patients now under observation. They are mother and daughter. Both have the same degree of virginal enteroptotic habitus (Rövsing, 2), water trap stomachs of equal size and degree, and similar colons. Abdominal radiographs are homologous. As a result of life's extreme activity and bipedism, the mother fell heir to the usual ills that attack people whom the Creator has endowed with such an intestine; she survived successfully a suspension operation on the colon and stomach and today is as active as ever. Their abdominal radiographs today are not homologous, but the daughter has been brought up to efficiency by means of abdominal support and posture, and especially elevation of the foot of the bed.

Another instance, seen personally with Dr. Le Wald, two brothers with an equal degree of dilated mobile cecum, may be cited. There is another instance, in the author's experience, of a brother and sister with congenital duodenal stenosis. We are very young in our gastrointestinal studies and need more thorough investigation into the alimentary tract of families before making positive statements. For example, the habitus enteroptoticus is more prevalent in some families than in others and, like other anatomical characteristics, obeys undoubtedly the Mendelian law.

This leads up to a very important connecting link, the frequency of chronic appendicitis in enteroptotic subjects. We are all more or less guided by our own experiences, and therefore I cite from my own series of cases of chronic intestinal toxemia from a paper read in January, 1916 (3). In a series of 136 cases of this disorder, there were thirty-three or twenty-five per cent. in whom a previous appendicectomy had been performed. In subdividing the cases into enteroptotics and nonenteroptotics, it was found that thirty-one, or nearly eighty per cent. of the appendicectomies were in enteroptotics, and nine, or about twenty per cent. were in nonenteroptotics. This is a significant fact and leads us to infer that the poor enteroptotic has a greater liability to appendicitis than the nonenteroptotic. This applies more literally to chronic than to acute appendicitis.

Bacterial infection as the exciting cause of an inflamed appendix, is an accepted fact. Among the bacteria that have been found as a cause of appendicitis, are the proteus, Bacillus subtilis, Bacillus capsulatus, Bacillus fusiformis, a diphtheroid bacillus, Bacillus tetani, Coccus conglomeratus, actinomycosis, pneumococcus, tubercle bacillus, streptococcus, staphylococcus, and last and probably most important, Bacillus coli communis.

Very many authorities agree that the colon bacillus is the most common factor in appendicitis; among them, John Deaver (4), John C. Da Costa (5), C. C. Choyce (6), Kelly and Noble (7), Richard Warren (8), W. H. Battle (9), and G. Mumford (10). The epidemiology of appendicitis is

*Read before the American Therapeutic Society, Detroit, June 10, 1916.

also discussed, and Warren mentions the influenza bacillus and Rose and Carless (11), the streptococcus in epidemics. Edward C. Rosenow (12) has produced appendicitis by inoculation with the streptococcus isolated from appendicitis, demonstrating apparently the selective action of bacteria.

Let us study Bacillus coli. Deaver says it is more frequent in chronic than in acute appendicitis, and has found it in pure culture in seventy per cent. of acute appendicitis and in ninety per cent. of chronic appendicitis. It has been found accompanied by the staphylococcus and the streptococcus, the latter very rarely in chronic cases. The staphylococcus alone is most infrequently found in acute or chronic cases.

Bacillus coli is known as a harmless and necessary organism in the gastrointestinal tract. Why then should it be considered dangerous? We quote Da Costa, who says: "Colon bacilli which normally inhabit the appendix are harmless when the appendix is healthy, but become active for harm when the diverticulum is bruised, obstructed, irritated by the presence of uric acid, congested because of the chilling of the cutaneous surface of the body, or distended by the ingress of the colonic fluid. It seems probable that the flatulent distention of the colon may be responsible for forcing fecal matter in quantity into the appendix and may lead to plugging of the opening."

What, if any, is the relationship between chronic appendicitis and chronic intestinal toxemia? It is interesting to note the change of thought along this line during the past decade. In 1905, Deaver stated that "he thinks constipation does not play a very important role in the causation of appendicitis." He mentioned at that time gastroenteritis, dysentery, typhoid, and influenza as predisposing causes, and traumatism, lead poisoning and intestinal parasites as exciting causes. Ten years later, we find that the chief responsibility is fastened upon Bacillus coli.

Ten years ago, Deaver said: "In some cases of long continued and marked constipation, it is possible that the increase in virulence of Bacillus coli communis that has been encountered in that condition, may be remotely connected with the development of this condition."

The appendix is only a part of the large intestine. As Warren expresses it, "it is no more than the relic of the cecum of our herbivorous ancestors. Removal of this relic appears to make no difference to the metabolism of patients thus deprived." There are other theories of the function of the appendix, such as lubrication, peristalsis, etc. The dangers of inflammation of this peculiar anatomical and rudimentary organ seem to justify its removal, whether it is normal or abnormal, during a laparotomy.

If the appendix belongs to the large intestine, it is natural to suppose that it will share in any diseased condition of that organ. Warren states that "appendicitis may be part of an inflammation of the large intestine (colitis) sometimes as a cause, at others as a sequel of this, and naturally its removal will have different results in the two conditions." He does not mention the condition of chronic intestinal toxemia in relation to chronic appendicitis.

"A few years ago, my appendix was removed for this trouble, but I am no better." What a common complaint and one that many of us hear almost daily! This is a sin of the profession and one that has been and still is committed by surgeons and physicians alike. A chronically diseased appendix should be removed, but the underlying condition, whether it be cause or effect, should also be corrected. It is the false security that the patient feels after the operation upon the assurance, "you are cured," that leads to the damage. I believe that time will demonstrate the proper treatment of the underlying intestinal toxemia, and the result will place the patient in a much better physical condition or even render the appendicectomy entirely unnecessary.

Da Costa's premonitory symptoms of appendicitis are similar to those of intestinal toxemia, as so understood. He describes them as "constipation or diarrhea, flatulence, nausea, anorexia, dyspepsia, coated tongue, weakness, general gastrointestinal uneasiness, colicky pains about the umbilicus, and perhaps some tenderness and a sense of weight, soreness, or uneasiness in the right iliac fossa." This is obviously a dividing line between the two conditions of appendicitis and intestinal toxemia. The symptoms characteristic of acute appendicitis are so well known, even to the inexperienced student, that they could not possibly be confounded with those of chronic intestinal toxemia. With the classical symptoms present it would be nothing short of gross carelessness not to operate, but with only the first set of indefinite symptoms a complete study of the case, including the x ray, should be instituted.

In our series of 136 cases, reported in January of this year, there were thirty-three patients, or twenty-five per cent. who had had appendicectomy previous to coming to the author. Whether the operation was justified or not, the majority of these patients understood that the operation was to end their trouble, but the results showed only slight or no improvement. The reasons were evident in a number of cases, as illustrated by four histories detailed by the author. The strong, classical symptoms of chronic appendicitis resolved themselves into those of chronic intestinal toxemia and disappeared under treatment.

Da Costa says: "In those rare cases of typhlitis occasionally encountered the symptoms are much milder than in appendicitis; the temperature is not much elevated, the pulse rate is only slightly accelerated, the leucocytosis is not marked, there is seldom rigidity, there may be tenderness, but seldom pain. Pain, when present, is colicky rather than continuous. There may be a doughy mass or a mass feeling like an air cushion in the right iliac fossa. Chronic typhlitis causes muscular atony and intestinal stasis." Our experience is similar to that of Da Costa, with the important exception that cases of chronic typhlitis are not "rare." This is perhaps due to the surgeon's standpoint which is one side of the question only. There should be no "medical side" nor "surgical side," for the subject is neither medical nor surgical, it is both. The

leading textbooks on surgery and medicine are too one sided; let us therefore place this before our students in the proper light.

Rose and Carless state that changes in the cecum and sometimes a generalized typhlocolitis often accompanies appendicitis. "It is in these cases where the cecum and colon are inflamed and tender as well as the appendix, that the most careful discrimination is needed in order to prevent needless operations which will not improve the patient's condition."

As the result of the study of my cases of appendicitis and chronic intestinal toxemia, where both conditions were present, the following classification suggested itself: 1. Cases where a previous appendicectomy had been performed without relief of symptoms of toxemia; 2, cases of cecal disease and toxemia resembling chronic appendicitis; 3. cases of chronic intestinal toxemia which developed into appendicitis while under observation. The following are illustrative of previous appendicectomies without relief of the symptoms of chronic toxemia:

Case I. G. A. K., male, aged thirty-three years, traveling salesman. Diarrhea and fermentation for twenty years, constipation developing in the last few years. Appendicectomy in 1910. Diagnosis: Enteroptosis, water trap stomach (13), chronic intestinal toxemia, and skin infections. Treatment: Abdominal support, posture, diet, agar, and Bacillus bulgaricus culture. Eleven doses of autogenous colon vaccines, with slight reactions. Autogenous staphylococcus vaccines for pyogenic skin and glandular infections. Result: Slow, but marked improvement.

Case II. S. K., female, aged thirty-eight years, single. For fourteen years very severe constipation and attacks of unconsciousness with convulsions, progressive, as many as eight or ten daily. No hereditary history of epilepsy. Flatulence and abdominal discomfort. Appendicectomy one and a half year ago, with no relief. Diagnosis: "Epilepsy" of intestinal origin. Dilated and residual cecum and stomach. Severe indicanuria, and putrefaction in stools. Treatment: Diet, colon massage, catharsis, hygiene, and occasional doses of bromides. Fifty injections of autogenous colon vaccines, sensitized at first and then nonsensitized, followed by severe reactions, local and general. Results: Marked improvement, no seizures for one year, then relapses. Advised operation on colon. Gradual improvement again. Kidney and liver functional tests, and chemical examination of the blood showed apparently normal condition of those organs.

Case III. T. D. M., male, aged thirty-one years, boot black. For ten years diarrhea, abdominal cramps, and discomfort. Headache, flatulence, gurgling, and general tenderness over abdomen. Streptococci and colon bacilli in the feces. Diagnosis: Chronic intestinal toxemia, long kinked sigmoid. Probably liver and pancreatic disturbance; diagnosis not completed. Indicanuria. Treatment: Colon lavage, tonics, salol and castor oil, diet and hygiene. Abdominal compresses and mineral oil. Thirteen doses of autogenous streptococcus vaccine, obtained from the feces, with severe reactions and no improvement. Eleven doses of autogenous colon vaccines and five injections of sensitized autogenous colon vaccines gave but slight improvement. The patient then disappeared for a while and returned after an appendicectomy had been performed by another doctor, with no relief to symptoms. The pathological findings were chronic appendicitis and Jackson's veil. Further studies contemplated in the direction of the liver and pancreatic derangement.

Case IV. A. J. L. E., female, aged forty-six years, single, school teacher. "Weak stomach" and headache since childhood. For fifteen years after a severe mental shock, suffered from abdominal distress, hemicrania, gradually increasing mental depression, and melancholia. During the past two years, condition had been unbearable; always constipated. Eight years ago, appendicectomy and removal of fibroids. No improvement. Blood pressure about 240 mm. Diagnosis: Severe chronic intestinal toxemia. Treatment: Operative reconstruction of the the colon. Result: Marked improvement for a year. Returned to work almost immediately, against advice. Relapse at the end of a year, with symptoms of infection of the remainder of the colon. Relief by autogenous colon vaccines, twenty-five injections with marked reactions. She had not lost a day's teaching during the past year. Blood pressure was lowered, on an average below 200, extreme limits, 220 to 150. Complete examination of the blood was made by Doctor Gettler, of Bellevue Hospital, and showed high hemoglobin, low noncoagulable nitrogen (28.4 mg.), low urea nitrogen (10.0 mg.), low uric acid (0.62 mg.), low creatinin (0.08 mg.), normal creatine, low chlorides (368 mg.), and low sugar (57.0 mg.). The serum showed a high freezing point, normal conductivity, refraction and specific gravity, and normal carbon dioxide. The urine, with the exception of low nitrogen content, was normal. The renal function test (phenosulphophthalein) showed fifty per cent. excretion at the end of the second hour. The kidneys therefore appeared to be functioning normally.

Case V. G. A. L., female, aged forty years, married. Constipated all her life, with cascara and enemata habits. Operations: Ten years ago, ovarian cyst removed; nine years ago appendicectomy for chronic appendicitis. No improvement. Symptoms beside constipation had been headaches, dullness, lack of mental poise, flatulence, backache, and occasional vomiting. Diagnosis: Residual stomach and cecum, sluggish colon, dilated sigmoid, and chronic intestinal toxemia. The menopause was partly responsible. Treatment: Diet, colon massage, and autogenous colon vaccines. Result: Steady improvement and cure.

Case VI. E. N., female, aged twenty-six years, single, school teacher. Constipation for years, occasional attacks of diarrhea, vomiting every two weeks, headache, flatulence, abdominal pain, and soreness in the right hypochondrium. Appendix removed several years ago without relief of symptoms. Diagnosis: Severe grade of enteroptosis, water trap stomach (13) with a ptosis of seventeen cm. Treatment: Posture, abdominal support, and diet. Result: Slow improvement.

Case VII. C. E., female, aged thirty-nine years, single. This was a similar case of marked enteroptosis, water trap stomach, with a drop of seventeen cm. All the symptoms of chronic intestinal toxemia present for years. Five years previously, appendix removed for recurring attacks of chronic appendicitis. No relief from symptoms. Had been slowly improving under treatment for chronic intestinal toxemia.

Case VIII. M. B., female, aged thirty-eight years, single, domestic. For seventeen years had had pain in the right iliac region, constipation, and alternating diarrhea. Operation, two months ago, for chronic appendicitis. No improvement and constipation worse. Diagnosis: Marked enteroptosis, water trap stomach, residual cecum, and long sigmoid. Toxemia marked. Treatment: Unsatisfactory on account of imperfect control; the patient disappeared.

The following case histories have been classed under chronic intestinal toxemia resembling chronic appendicitis. They have been closely followed so that, in our judgment, intestinal toxemia and constipation are the predominant factors.

Case IX. A. P., male, aged thirty-one years, confidential agent, single. For the past three years, had had marked constipation, abdominal cramps, pyorrhea, and decayed teeth. The condition would improve after treatment in a European spa; but had been getting progressively worse. When first seen, had a severe attack of obstipation, abdominal cramps, especially in the right iliac region, heaviness, coated tongue, and finally a severe sciatica. Marked tenderness in the right iliac region, crepitation and splashing over the cecum. Diagnosis: Marked enteroptosis, residual stomach and cecum, long atrophic sigmoid, and severe chronic intestinal toxemia. Large doses of the coal-tar products had no appreciable effect on the pains, which responded quickly to the first injection of autogenous colon vaccine. Symptoms improved greatly by diet, abdominal support, posture, and repeated doses of colon vaccine. Results: Eight months later, abdominal symptoms had disappeared and the bowels were moving well.

Case X. E. K. W., female, aged twenty-nine years, married. The history was a typical one of constipation and stomach trouble following confinement to bed after a fractured hip, five years ago. Alternating constipation and diarrhea, with marked colica mucosa. One year ago, rest in bed and forced feeding resulted in increase in weight, but no improvement in symptoms. Patient was enteroptotic, with marked tenderness and crepitation over the cecum, and the whole abdomen was exquisitely tender. Water trap stomach, with large residue at six and one half hours. Appendix outlined, retrocecal to the right, and apparently adherent. Very long sigmoid, cecum and sigmoid very sluggish. Treatment: Abdominal support, posture, diet, stomach and colon lavage, and autogenous colon vaccines improved the conditions very much in ten months. Chronic appendicitis had been carefully considered, as the symptoms pointed very strongly that way. Radiographs of the colon, however, showed marked improvement in that organ, and the necessity for operation seemed to be past.

Case XI. H. R. G., female, aged thirty-nine years, married. Had been constipated all her life and accustomed to rich food. Cascara habit for years. Headaches and flatulence, pain and soreness in the right iliac region. Diagnosis: Moderate enteroptosis, residual cecum and appendix, dilated sigmoid, and chronic intestinal toxemia. Treatment: Diet and hygiene, colon massage, and autogenous colon vaccines. Results: Steady improvement and regularity of bowels after two months. Abdominal tenderness disappeared. Relapse, but rapid improvement on resumption of treatment. Second series of radiographs demonstrated the improvement of the colon and appendix constipation.

Case XII. B. R., female, aged thirty-five years, single. Family history of constipation. Has been constipated since childhood, no normal movement without catharsis. Chief complaints, flatulence and nervousness. Later patient developed joint pains and joint crepitus. Cecum was large, very tender, and crepitating. Radiographs showed large residual cecum, appendix outlined in one plate and retrocecal, three days' stasis in transverse colon. The diagnosis of chronic appendicitis was carefully considered and ruled out only after considering behavior to treatment and confirmatory radiographs. Diagnosis: Dilated, residual cecum, colon constipation, and chronic intestinal toxemia. Treatment: Diet and hygiene, colon massage, and a course of autogenous colon vaccines which helped materially. Results: Slow improvement with frequent relapses. Two years later, symptoms still present, though less marked.

Case XIII. W. L. R., male, aged thirty-five years, married. Patient felt perfectly well up to five years ago, when he had a sudden attack of nausea, weakness, and cold sweat after eating scallops. He then acquired a nervous exhaustion with peculiar obsessions. Since then he had had great fear of entering strange places, of traveling, and of entering into company, and, on this account, was about to give up business. No appetite, "convulsive retchings" at the thought of eating, constipation, and flatulence. Radiographs showed marked enteroptosis, water trap stomach, and a slight residue of bismuth after seventy-one hours in the appendix, although the colon was empty at that hour. Diagnosis: Neurasthenia, with mental depression and obsessions, caused by chronic intestinal toxemia. Enteroptosis, with the possibility of chronic appendicitis. Treatment: Abdominal support, posture, diet, and hygiene. Autogenous colon vaccines regularly for nearly a year. Results: No improvement for the first two months; then slow but marked improvement. At the end of a year, much improvement in mental condition, but still some irregularity of the bowels. Patient greatly in need of a vacation, which he had not had for four years. No positive evidences of appendicitis to date.

The following case history may be of value as demonstrating probably a close relationship between appendicitis and chronic intestinal toxemia.

Case XIV. M. McD., aged twenty-seven years, colored, single, domestic, had had severe constipation for years. At first presented herself for strangulated hemorrhoids. Hemorrhoidectomy in 1911. Following operation, had cramplike pains in abdomen, flatulence, vomiting regularly after eating, vertigo, and rapid loss of weight. Radiographs showed a rapidly emptying stomach, marked coloptosis, deep in the pelvis. The cecum dilated, the appendix outlined, long and bent on itself, and retained bismuth for six days after the cecum had emptied itself. The sigmoid and rectum, markedly dilated, were the principal sites of the constipation. The interesting part of this radiographic study was the apparent backing up (anastalsis) of the bismuth meal into the cecum and ascending colon on the second day. There were no classical symptoms of appendicitis, yet we dared to prognose an attack of appendicitis in the near future from the radiographic findings. Four months after there occurred a typical attack of acute appendicitis, and an acutely inflamed swollen organ was removed. Suspension of the colon was done at the same time. In a review of the results on our later cases with a similar bowel condition, the author believed that a reconstruction of the colon was the proper procedure. Microscopical examination of the appendix showed acute catarrhal appendicitis, with a bend but no obstruction. The wall of the appendix must have shared in the atony of the large bowel, which might explain the retention of the bismuth in the organ.

CONCLUSIONS.

1. The necessity of the careful study of all cases diagnosed as chronic appendicitis and the use of the x ray in every case.

2. The symptoms of chronic appendicitis and cecal disease are often very similar.

3. Cooperation between surgeon and internist in the study and treatment of these cases, before and after operation (no one man's case).

4. The proper treatment for chronic intestinal toxemia may clear up symptoms resembling chronic appendicitis.

5. Autogenous colon vaccines should be tried in every case.

6. The internist should be always on guard for appendicitis in every case of chronic intestinal toxemia, and the surgeon for chronic intestinal toxemia in the case of appendicitis.

7. Our medical student should have instruction along these lines and be taught not to diagnose intestinal conditions on symptoms alone.

CHRONIC GONORRHEA IN THE MALE.*

By Joseph Kaufman, M. D.,
New York.

It is not the purpose of this paper to present any new or startling facts concerning so called chronic gonorrhea. It is rather an effort to classify our knowledge, and a plea for more scientific and rational diagnosis and treatment. The classification of all lesions, urethral, periurethral, annexal, gonorrheal, and postgonorrheal, under the single term, chronic gonorrhea, is inexact and unscien-

*Read at a meeting of the Alumni Association of St. Mark's Hospital, New York, March 10, 1916.

tific. The application of so generic a term does not take into account the variety or combination of pathological lesions which may exist in a given case of gonorrheal or postgonorrheal disease of the lower genitourinary tract. The term is a misnomer and should be abolished.

Given a case of acute gonorrheal urethritis, what happens? For the first twenty-four to thirty-six hours the gonococcus remains on the surface of the urethra. It begins, thereafter, to burrow down into the deeper tissues, i. e., the crypts of Morgagni and the glands of Littré, into the submucosa, and even into the loose periurethral tissue. The surroundings are congenial and all the factors favorable to growth are present. Multiplication is both rapid and prodigious. The effort of the organism to overcome the invading host is evidenced by the usual signs of inflammation, viz., pain, heat, swelling, and pus. The infection travels rapidly from the meatus to the bulbomembranous junction of the urethra, and if the process goes still further, the prostatic urethra, the bladder, the prostate, seminal vesicles, and one or both epididymides are invaded. The patient seeks relief and is put under treatment. After a variable length of time, the discharge ceases, the urine becomes clear, and the patient is dismissed cured.

If the treatment has been successful, he has no further trouble, but if the reverse is the fact, what happens? He notices either a drop of actual pus, mucus, or mucopus at the meatus before the first urination of the day, the so called "morning drop," and very often before every urination during the twenty-four hours. The urine contains shreds and is often cloudy from mucus or pus. Indulgence in intercourse, coupled with the free imbibition of alcohol, is followed by a return of the acute symptoms. Frequently the patient cannot assign any tangible reason for the recurrence. This need cause no great doubt. The treatment has been sufficient only to clear up the superficial inflammation and has not affected the gonococci beneath the surface of the mucous membrane. The removal of the noxious influence of the remedial agents is followed by a rapid multiplication of the gonococci with a reappearance of all the signs of acute inflammation. This succession of events may be, and often is repeated at intervals, and may go on for a long time and accounts, in a great measure, for the current doubt as to the curability of chronic gonorrheal affections in the male.

In the intervals between the recurrent, subacute attacks, the urethra and annexa, if they have been involved, are in a state of chronic inflammation. Often the patient seeks relief from his symptoms, but unfortunately, just as frequently neglects to do so, either through ignorance or carelessness or both. Most physicians are more or less familiar with the so called routine treatment of chronic gonorrhea, namely, the passage of sounds, prostatic massage, irrigations, instillations, etc., and the patient is promptly put through such a course of treatment.

This indefinite, routine treatment is, of necessity, the logical sequel of inexact and indeterminate diagnosis and explains the unsatisfactory results so often obtained. Definite curative measures, however, applied for definite reason and with an exact knowledge of the pathological lesions, will yield uniformly good results.

The classification of the lesions encountered, which I use, is not new. It is based on the pathological findings and is as follows:

1. Chronic anterior urethritis.
2. Chronic posterior urethritis.
3. Chronic prostatitis.
4. Chronic seminal vesiculitis.
5. Chronic relapsing epididymitis.
6. Chronic cystourethritis or trigonitis (gonorrheal).

The above enumerated conditions are further classified as:

a. Gonorrheal or specific (when the gonococcus can be demonstrated. Usually the gonococcus is associated with staphylococci or micrococci).

b. Nongonorrheal or nonspecific (when only the milder saphrophytic organisms can be demonstrated).

c. Postinflammatory or postgonorrheal (when organisms cannot be demonstrated, either morphologically or culturally. In these cases the patient presents lesions which are the direct result of previous inflammatory processes.)

The definite lesions to be found in the first three of these conditions are as follows:

1. Chronic anterior urethritis: a. Folliculitis (chronic inflammation of the crypts and glands of Littré). *b.* Infiltrates, mucosal, submucosal, and periglandular (the superficial forms include granulations and erosions of the mucous membrane). *c.* Stricture (a further development of the process of infiltration with the formation of organized connective tissue).

2. Chronic posterior urethritis: a. Colliculitis (diseases of the verumontanum): I. Simple congestion and hyperplasia; II, granulomatous excrescences, erroneously called polyps; III, retention cysts, usually arising from the utricle; IV, atrophy, associated with cicatrices.

b. Granulomata (so called polyps) arising from the lateral walls and floor of the urethra;

c. Cysts, usually arising from the occluded Littré glands and occasionally from the sphincter.

d. Dilated prostatic ducts.

3. Chronic prostatitis: a. Follicular: I. Specific (gonorrheal); II, Nonspecific (congestive).

b. Parenchymatous: I. Specific (gonorrheal); II, nonspecific (congestive).

It is to be borne in mind that it is most unusual to find a sharply defined and localized lesion. Usually, where a case has persisted for some time, the greater part of the tract is involved, with a preponderance of lesions in one part and the majority of subjective lesions pointing to that locality.

A brief consideration of such a formidable array of pathological lesions, any one or all of which may exist, should convince us of the absolute necessity of a careful and detailed examination in every instance, before active treatment is begun.

GENERAL EXAMINATION OF THE PATIENT.

History. A careful and detailed history of each case will furnish many clues to the alert physician. The first question should deal with the chief complaint. As a class, these patients present, as the most prominent symptom, any one or combination of the following:

Morning drop, which may contain pus cells and bacteria, but usually consists of mucus and epithelial cells. It may have its origin in any part of the tract.

Frequency of urination, due to the chronic congestion of the parts, or, at times, to an inability completely to empty the bladder at each urination.

Tickling at the meatus or in the urethra, which may arise from a lesion in the anterior urethra, but more often from the prostate or posterior urethra.

Pain in the perineum, suprapubic region, or rectum, denoting almost always a lesion of the posterior urethra, particularly the verumontanum and less often the prostate and seminal vesicles.

Abnormalities in the stream of urine, i. e., distortion of the stream, inability to start the stream, or dribbling after completion of the act. Such abnormalities may usually be traced to obstructive causes, notably stricture and prostatic enlargement.

Dysuria, which may be due to the presence of a slight inflammation in some part of the urethra or to the passing of hyperacid urine over eroded surfaces.

The second question should be the duration of symptoms and the number of acute attacks.

The appended figures illustrate graphically the importance of this question. In a series of 100 cases, the following was found:

Number of Acute Attacks.

1	7 per cent.
2	44 per cent.
3	36 per cent.
4	8 per cent.
5	5 per cent.

Duration of Symptoms.

1 year	9 per cent.
2 years	19 per cent.
3 years	9 per cent.
4 years	7 per cent.
5 to 9 years	21 per cent.
10 to 14 years	19 per cent.
15 to 20 years	16 per cent.

To enlarge, eighty-eight per cent. of the cases had from two to four attacks of "acute gonorrhea"; sixty-five per cent. had symptoms covering a period of from one to five years, while eighty-four per cent. presented symptoms over a period of from one to ten years. Of the cases under consideration, twenty per cent. appeared, at the time of examination, with acute symptoms. The average case gave a history of having had a "new gonorrhea" every few months, while in a considerable number there was a history of the reappearance of acute symptoms without exposure.

In the light of our experience we believe that, in the majority of cases with acute symptoms and a history of frequently recurring attacks, we were not dealing with new infections, but simply with exacerbations of subacute or chronic processes in some part of the tract.

LOCAL EXAMINATION OF THE PATIENT

When practicable, the patient should be examined before the first urination of the day. At other times the urine should be retained by the patient, for at least three to four hours before the examination. The first thing to be noted is the urethral discharge. The urethra should be stripped, starting at the perineum and ending at the meatus, and whatever secretion is secured should be transferred to a glass slide for examination. The Gram method should be used for staining, as only in this manner can we be reasonably certain of the identity of the organisms.

The size of the urinary meatus should next be ascertained. It is astonishing to note the number of patients who are treated for recurrent attacks of urethritis without attention being given the small, inadequate meatus. This is one of the most frequent single causes of relapse or recurrence. If the meatus is too small to admit any instrument of less than No. 26 F. calibre, meatotomy must be performed before the examination proceeds and need not delay such examination.

Study of the urine. The usual two glass test will simply give the information that there are shreds, pus, or mucus in the urine. For an accurate determination of the origin of shreds or pus or mucus, one of the multiple glass tests must be performed. The Wolbarst five glass test has, in our hands, proved to be the most advantageous and satisfactory for this purpose.

Urethral shreds present certain characteristics which allow, occasionally, of their localization. Small, granular flakes, which float in the urine, usually arise from the anterior urethra and are composed of superficial epithelial cells and leucocytes. Threadlike shreds, which sink to the bottom of the glass, also have their origin in the anterior urethra and consist, for the greater part, of leucocytes. The comma or tadpole shred usually arises from an ulcerated or granular area, which most often is present in the posterior urethra and occasionally in the anterior portion. The dot or head is composed of pus cells, while the tail contains epithelium. The long, filmy shreds come from the prostatic or ejaculatory ducts and consist of mucus, leucocytes, epithelium, and often a few spermatozoa. Irregular and broken shreds usually originate in the anterior urethra and denote a chronic inflammatory process most often of the type which exists posterior to a stricture.

Palpation of the prostate and seminal vesicles. Palpation of the prostate should reveal definite information as to size, consistence, and pain. The normal sized prostate, if there is such, is solely a question of relative values. If the lateral lobes are flat and not prominent, if the gland substance is soft and flaccid and is not painful on moderate pressure, it may be said that the prostate is normal in size to rectal palpation.

A diseased prostate may present one of many appearances. The chronically congested, nongonorrheal prostate, as well as the gonorrheal, parenchymatous organ, presents an uniformly enlarged gland, dense, and at times boggy and painful to the touch. In the gonorrheal type, a moderate amount of pressure is followed by a free flow of prostatic secretion, which contains normal prostatic fluid, pus, epithelium, and inflammatory débris. In the follicular type the gland is enlarged, one lobe is more prominent than its fellow, lumpy and hard to the touch. Pain on pressure is variable, and stripping of the gland is not so productive of secretion as the parenchymatous form. The lumps represent groups of acini which have been infected during the acute stage. The interacinous tissue, or stroma of the gland, is not so greatly involved.

The normal seminal vesicle is usually not palpable. When it is inflamed and enlarged, the fundus may be felt above and to the outer side of the prostate. The information revealed by palpation is indefinite at best. If we feel the vesicle, it is said to be enlarged. Inflammatory thickening around the vesicle is often present and may be mistaken for actual involvement of that organ itself.

Secretion which appears at the meatus during

palpation of these organs should be caught on a slide and submitted to microscopical examination.

Study of the urethra. The study of the urethra is the final step in the examination and should begin with a determination of the calibre of the canal. It is assumed that the meatus is large enough to admit a No. 26 F. instrument, and if not, that a meatotomy has been performed.

The instrument of choice is the bougie-à-boule. I prefer to begin with No. 26 F. and pass the instrument as far as the bulbomembranous junction of the urethra, and from there on into the bladder. If an obstruction is met, successively smaller sizes are used until one passes without marked difficulty. As the instrument is withdrawn, the shoulder of the bougie will be felt to impinge on the obstruction. The exact site of obstruction is thus easily found. The character of obstruction can often be determined only by urethroscopic examination, as it is not only stricture which may cause a diminution in the calibre of the urethra; infiltrations in the mucosa or in the periurethral tissues may impinge on the canal and lead us to erroneous conclusions. If the obstruction is of such extent as to prevent the passage of even the smaller sized instruments, filiform bougies must be used to enter the bladder.

After the localization of obstructions has been completed, it is good practice to pass the largest, straight steel sound which the urethra can comfortably admit. The penis is put on the stretch and the urethra palpated with the sound in place. In this manner we often detect, still more clearly, glandular enlargement and periurethral infiltration.

For the urethroscopic examination the patient is prepared in the lithotomy position and the water-dilating cystourethroscope employed. With this instrument the neck and base of the bladder, the prostatic, membranous, and even pendulous portions of the urethra may be closely examined. If there is sufficient reason, the anterior portion of the urethra is examined further, using an air dilating type of instrument for that purpose.

With such an examination it is a comparatively simple matter to clinch the tentative diagnosis which should have been partly made as a result of the preceding steps. Abnormalities of the verumontanum (i. e., enlargements due to hyperplasia, contracture, granulomatous excrescences, so called polyps, cysts), or dilated prostatic ducts, ulcerations, granular areas, chronically inflamed Littré glands, soft and hard infiltrations, and strictures may be definitely visualized and localized. With such information at hand the physician is in a position to begin treatment with the assurance of definitely successful results.

TREATMENT.

The treatment must aim to accomplish two things, namely, 1, the disappearance of all organisms, and, 2, the resorption of all inflammatory or postinflammatory lesions with a return to the normal of all parts of the tract. The successful attainment of these prerequisites for a cure, depends solely, to my mind, upon one thing, i. e., successful cooperation with the natural forces of each individual. The treatment should, with few exceptions, aim to cause a mild hyperemia in the parts. Such hyperemia is attended by a mild leucocytosis. The phagocytes attack the bacteria and render them inert; the increased flow of blood to the parts aids in the resorption of the round cell infiltration which accompanies chronic inflammatory processes. Thus are strictures and infiltrates softened, glandular enlargements reduced, and erosions and ulcerations encouraged to heal. All therapeutic measures are to be employed only so far as they aid in the establishment of such hyperemia.

Before speaking in detail of the various therapeutic measures, it is well to sound a warning. The tendency, in the treatment of chronic affections, is to attempt to do altogether too much. A large number are overtreated and consequently not at all benefited. In my opinion it is much more profitable to sin on the side of omission than to injure the patient by errors of commission. Gentleness in all maneuvres is of the greatest importance, and this applies to the passing of sounds or other instruments, massage of the prostate as well as to the strength of solutions employed.

Lastly, the physician must impress upon the patient the impossibility of effecting a rapid cure. Nature works slowly, and as our treatment aims to be an aid of natural forces, it is to be expected that all cases will require considerable time to be brought to a successful conclusion.

Chronic anterior urethritis. As detailed before, the definite lesions of chronic anterior urethritis are, *a,* folliculitis, *b,* infiltrates, and, *c,* stricture. The most useful measure in the treatment of these lesions, as a class, is dilation, but it must be used with a keen insight and knowledge of the dangers as well as of the benefits accruing to its intelligent application. Careful and gentle dilatation is always followed by a mild hyperemia. If there are any bacteria in the lacunæ and glands, they are attacked by the leucocytes. Scar tissue, whether surrounding periurethral glands or in the mucosa itself, is softened and soon approaches the normal elasticity. Forceful and energetic dilatation nearly always has a deleterious effect upon the tissues. It is followed by congestion rather than by hyperemia, with a resulting round cell infiltration; simple erosions are transformed into veritable fissures and their healing, delayed instead of being encouraged, is attended by scar tissue formation.

The instruments used for this purpose are the Kollmann dilator and the steel sound. I use the dilator only when there is a moderate amount of infiltration and of recent origin. For more advanced infiltrations, strictures, and stubborn cases of folliculitis, I prefer the steel sound.

The dilator is inserted into the urethra, closed, at No. 22 F., and gradually opened to any desired size. To be successful, the dilatation must be gradual and gentle. At the first application I rarely dilate beyond No. 28 F. The instrument is allowed to remain in place for at least ten minutes—longer if practicable. At the next application the instrument is opened to a few degrees below the last maximum, and after a few moments is gradually advanced one or two degrees beyond that point. This is repeated at suitable intervals until there is no difficulty in reaching No. 35 F.

Following the withdrawal of the instrument, which should not occur until it has been closed, the urethra is stripped and any secretion which may appear is transferred to a slide for microscopical examination. If bacteria can be demonstrated, one of the silver proteid or colloidal iodine solutions is injected into the urethra and retained for five minutes. If bacteria cannot be found, the urethra is copiously irrigated with potassium permanganate or silver nitrate solution in weak strengths.

For cases of actual stricture, the steel sound surpasses the dilator in usefulness. The smallest sound which can be introduced without undue traumatism, is used. After a few moments the next size larger is passed. At subsequent visits the same sized sounds are used and followed by the next size larger, and so on until the urethra admits No. 30 F. without difficulty. We must take into consideration the size of the penis. Given a patient with a small organ, No. 28 F. is usually sufficiently large as the upper limit, while in patients with large organs, I often go as high as No. 32 F. The last sound used at each visit is allowed to remain in place for at least ten minutes, and after its removal the urethra is either injected or irrigated according to the indications.

Massage of the anterior urethra is the next most valuable therapeutic measure. The largest sized straight steel sound which can be easily passed into the urethra is used. The penis is put on the stretch, so as to obliterate all folds of mucous membrane. The finger can then palpate and distinguish all urethral and periurethral thickening. These areas are very gently, but withal very thoroughly massaged, care being taken that the mucous membrane is not unduly traumatized. Following such massage the urethra is stripped and the secretion examined for bacteria. If organisms can be demonstrated, I inject either one of the silver proteid or colloidal iodine solutions, to be retained for five minutes. When bacteria are not found the urethra is irrigated. It is remarkable to note, after a few such treatments, that the periurethral and mucosal thickening gradually disappear and the shreds in the urine become smaller and finer.

Direct application of medicinal agents through the urethroscopic tube is useful, if employed carefully and when indicated. The agent most often used is silver nitrate, in strength varying from one to twenty-five per cent. Solutions of fuchsin and weak iodine are used at times. For ulcerated areas I use silver nitrate, ten per cent., applied on a fine swab directly to the desired area. It is also of benefit, in this strength, when applied to the mouths of the glands of Littré. For simple erosions and granular areas I employ silver nitrate five per cent.

For cases of folliculitis which do not respond to the various measures already mentioned, fulguration gives very good results. The mouth of the gland is entered with a fulguration needle and the Oudin current applied for a few seconds. The current must not be too strong or applied for too long a period. Such applications should not be repeated oftener than once a week.

The bulbous portion of the urethra is one of the most prolific sources of lesions which aid in the prolongation of these cases. Because of their site, they often escape detection and for the same reason are difficult to treat. Dilatation of the posterior urethra with the Kollmann dilator followed by injection or irrigation is alternated with direct application of silver nitrate. These applications are best made at the same time that lesions in the posterior urethra are treated. The instrument is gradually withdrawn until the membranous urethra comes into view. Granulations and erosions abound in the cul-de-sac just anterior to the membranous urethra, and are medicated as they come into view on withdrawal of the urethroscope.

Chronic posterior urethritis. Diseases of the verumontanum occupy a prominent place among the lesions found in the posterior urethra. Simple hyperplasia, accompanied by congestion, is the most common pathological entity and is usually present along with chronic prostatitis and seminal vesiculitis. With the treatment of these last named conditions the verumontanum usually approaches the normal. Direct application, through the urethroscope, of silver nitrate, ten per cent., on a fine swab needs to be repeated but a few times in order to encourage such return to normal.

Atrophy of the verumontanum, associated with cicatrices, may be ameliorated. Constant and careful dilatation causes a resorption of the scar tissue and may be followed by improvement in the verumontanum itself. More often, however, the verumontanum does not regain its normal size.

Granulomatous excrescences from the verumontanum, erroneously called polyps, may be destroyed by the direct application of silver nitrate, ten to twenty-five per cent. Dilatation, with the Kollmann instrument or sounds, of the posterior urethra may aid in their destruction. Where these measures are unsuccessful the Oudin current, carefully applied, usually gives satisfactory results.

Retention cysts of the verumontanum may be destroyed by dilatation, but I usually find that recourse must be had to fulguration with the Oudin current. The cyst wall is penetrated and the current applied for a few moments.

The floor of the posterior urethra as well as the lateral walls are the sites of many lesions. Granulomata and cysts are found as well as in the verumontanum itself. Ulcerated and granulated areas are common. Direct application of silver nitrate, alternated with careful and gentle dilatation with recourse to fulguration only when indicated, are the measures.

Dilated prostatic ducts are common and are a source of great annoyance. They are to be found on the floor of the posterior urethra in almost every case of long standing in which the prostate is involved. I have, at various times, injected silver nitrate, weak iodine, and colloidal iodine solutions, and fulgurated, with but poor success. Constant prostatic massage, associated with dilatation of the posterior urethra, usually brings about an improvement. Mixed gonococcus vaccines are indicated in these cases and are to be used if the treatment outlined does not give satisfactory results.

For dilatation I use, as in the anterior urethra, the Kollmann dilator and the steel sound. When the

anterior urethra is not involved or has improved under treatment, I use the Beniqué curved sound for the posterior urethra. The dilator is used when there is little or no cicatrization. It is inserted into the urethra, closed, at No. 22 F., and gradually opened to the desired size. At the first application, unless there is difficulty, dilatation is carried up to No. 28 or 30 F., and at subsequent visits up to No. 40. It is to be noted that the posterior urethra is much more easily dilatable than the anterior portion of the canal. The dilator is left in place for at least ten minutes, closed, and withdrawn. In cases associated with dilated prostatic ducts and prostatitis, I always instil either silver nitrate, 0.5 to one per cent., one of the silver proteid or colloidal iodine solutions into the posterior urethra upon withdrawal of the instrument. In other cases I usually irrigate with a weak silver nitrate or permanganate solution, using the Janet syringe.

Where it is necessary to overcome cicatrization, I find that the steel sound is superior to the dilator. As in the anterior urethra, dilatation is gradual and gentle. The sound is allowed to remain in place for ten minutes and the posterior urethra either irrigated or injected, upon its removal, as the indications demand.

Chronic prostatitis and seminal vesiculitis. The treatment of chronic prostatitis gives, at times, brilliant results, while in other instances it is disappointing. To a great measure this is due to the manner in which each case is managed. Prostatic massage, in experienced hands, is a safe and satisfactory measure, while in careless hands it is a dangerous weapon.

Massage of the prostate is performed with a definite purpose in mind as to just what is to be accomplished. First, there is the actual, manual expression of the contents of the acini and ducts. Second, there is established a mild hyperemia which causes and aids in the resorption of inflammatory material and brings about a return to the normal in size, shape, and consistence. Further than this, careful massage exerts a beneficial influence on the posterior urethra itself. The hyperemia is evidenced here as well as in the prostate and so acts as an adjuvant in the treatment of lesions in that portion of the urethra.

The bladder is first filled with a warm solution of silver nitrate (one to 3,000) or permanganate (150 c. c.). The patient leans over a stool, the legs widely separated, and holds a glass under the penis. The finger should be well lubricated and gently inserted into the rectum. The massage must be gently, slowly, and carefully performed. To be of any benefit the massage should consume at least from three to five minutes. The finger begins at the upper limit or base of each lobe and is carried, firmly but gently, down to the apex. The finger then travels from side to side until both lobes have been covered. Only a moderate amount of pressure is needed to secure the desired results.

In cases of follicular prostatitis, which do not respond after a reasonable length of time, I often insert a suppository of iodine and potassium iodide into the rectum and then apply the high frequency current directly over the prostate for five to ten minutes, using a vacuum electrode. Following this, the bladder is filled with solution and the prostate carefully massaged. The heat engendered by the high frequency current, together with the action ot the iodide, seems to favor a more rapid absorption than is ordinarily secured by massage alone.

In other cases, especially where dilated prostatic ducts exist, it is well to dilate the posterior urethra before the prostate is massaged. In this manner we may facilitate the free escape of secretion from the acini and ducts.

Chronic seminal vesiculitis exists, very often, in such mild form as to escape detection. As a general rule, I endeavor to include the vesicles when the prostate is massaged. Where the process is further advanced, massage must be very gentle. As a matter of caution, the prostate or vesicles must never be massaged too vigorously, as I have seen many cases of acute epididymitis develop in the course of the treatment of chronic prostatitis when this rule was disregarded. The results from the operation of seminal vesiculotomy, as I have observed them, are not such as to encourage me in advising operation for the relief of symptoms said to arise from chronic seminal vesiculitis. Mixed gonococcus vaccines are used in conjunction with the treatment outlined.

Chronic relapsing epididymitis. The treatment of this condition is, first, prophylactic. Careful massage of the prostate and seminal vesicles will reduce the frequency of its occurrence, incidental to the treatment of lesions in these organs.

When it does happen, I have found that the best measure is multiple, subcutaneous puncture of the epididymis and then the external application of some counterirritant. Binding of the testicle around its long axis, with a rubber bandage after the manner of Keyes, is also very useful. Vaccines or serums may be employed in addition. The operation of vasotomy has been discarded by me in favor of the simple, subcutaneous puncture method.

Chronic cystourethritis. The treatment of this condition is incidental to that of other lesions in the posterior urethra and annexa. Irrigations with silver nitrate, the internal administration of some antiseptic, and careful regulation of the bowels are in order. Where colon bacilli can be demonstrated as added organisms, vaccines may be employed. At times, the neck of the bladder must be swabbed with silver nitrate, applied through the cystourethroscope.

Summed up, then, the treatment of chronic affections of the lower genitourinary tract in the male resolves itself into an application of suitable measures, in a definite manner, and with definite knowledge of the pathological lesions present. The keynote of all therapeusis is gentleness as well as precision. The various measures are alternated so as not unduly to irritate any one portion of the tract. The patient calls at intervals of about three to four days and only one portion of the tract is treated. At subsequent visits some other part is treated and so on until there is a distinct improvement in the entire picture. Persistence is essential and is a most important factor in a successful conclusion. Internal medication is rarely employed, except to meet some special indication.

THE PHYSICS OF THE HIGH FREQUENCY CURRENT.

By Albert C. Geyser, M. D.,
New York,
Professor of Physiological Therapy, Fordham University Medical College; Late Lecturer in Electrotherapy and Radiotherapy, New York Polyclinic School and Hospital.

In speaking of the physics of the high frequency current I shall take into consideration the fact that my audience is principally made up of physicians in general practice. I shall attempt to avoid, as much as possible, technical terms, but will explain their meaning if occasion arises. The underlying laws of electricity do not differ; they are the same for currents of low potentials or high potentials, for low frequencies or high frequencies, for unidirectional as well as alternating currents. It is essential to have a clear conception of such fundamental units of electrical measurements as the volt, the ampere, and the ohm.

For some unaccountable reason, the moment that electricity is mentioned, everything connected therewith seems to become obscure and difficult of comprehension. When the same terms are applied to something more familiar, however, they become clear and easy of comprehension. Let us suppose that we are dealing with an ordinary hypodermic syringe; the barrel is filled with a solution of morphine. When this syringe is held with the needle pointing downward, the fluid does not escape. The question is, Why not? For the same reason that when the needle is plunged into the tissue the fluid does not enter the tissue. In the first instance the atmospheric pressure against the needle opening prevents the escape of the fluid by resisting the force of gravity. In the second instance, to this resistance is added that of the density of the tissue into which the needle has been plunged. In order to overcome this resistance we use pressure on the piston. When the resistance of the tissues has been overcome by the pressure, then we have deposited into the tissues the contents of the syringe and we begin to appreciate the results or the effect of the morphine.

A volt is an electrical unit of pressure. An ampere is an electrical unit of the rate of flow. An ohm is an electrical unit of resistance.

It is plain now that we cannot have a rate of flow (amperage) of the morphine solution into the tissues without having an adequate amount of pressure (voltage) exerted upon the piston to overcome the resistance (ohms) of the tissue. We can appreciate the meaningless remark that a few thousand volts were passed through a criminal during an act of electrocution. It is equivalent to exerting much pressure upon the piston of an empty syringe.

Now that we understand the value of the terms volt, ampere, and ohm, we may attempt an explanation of the term, high frequency. We distinguish two main sources of supply, the direct current (DC) and the alternating current (AC). For the purpose of producing the high frequency current the alternating current is the one of choice. The ordinary alternating current derives its name from the fact that the current alternates its direction 120 times each second. This current flows in one direction for 1/120 of a second, then ceases entirely for an inconceivably short space of time, then directly changes its direction. When the current has thus flowed in one direction for 1/120 second and has changed its direction for another like period, it has completed its first cycle. We have therefore sixty cycles and 120 alternations during each second.

If such an alternating current is passed through a primary coil, inductions are set up in any secondary coil which may happen to be near it.

The primary coil consists of a relatively few turns of coarse wire, while the superimposed secondary consists of thousands of turns of fine wire. The ratio of these turns may be to each other as one is to 1,000.

This ratio of one to 1,000 is of considerable importance, for if we remember that our original current which passed into the primary coil was approximately 100 volts, then by multiplying this voltage with the ratio of 1,000 we have 100,000 volts coming from the terminals of the secondary coil. This increase of voltage in the secondary coil has been gained at the expense of amperage. Such a device as a primary current, inducing a secondary of higher voltage, is known as a "step up transformer." In the same manner, a current of high voltage and low amperage can be passed directly into the former secondary coil, the resulting induction in the former primary coil will be one of lower voltage and correspondingly higher amperage. Such an arrangement is therefore designated as a "step down transformer."

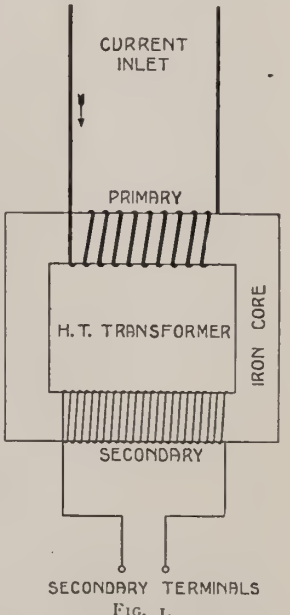

Fig. 1.

In the production of the high frequency current the primary current is at first stepped up to secure the necessary tension. A tension of 100,000 volts is sufficient for our purpose. Such a current is then led into a pair of Leyden jars or other similar condensers. A condenser is a device or arrangement where some electrical capacity such as tin foil, salt water, or even the human body, charged with an electric current, is separated by some nonconducting material such as air, glass, fibre, or hard rubber, from some other electrical capacity. A Leyden jar, therefore, is a perfect condenser. Here we have a glass jar which is a nonconductor. The inside is either filled with a solution of salt water or coated with a layer of tin foil. The outside of the jar is covered with tin foil. We have here two good electric capacities separated by the nonconducting glass.

The previously created high tension current is passed by a metal conductor to the inside of the Leyden jar. One terminal of the secondary coil ends in one jar, while the other terminal ends in the other jar.

Let us revert for a minute and recall to mind that we were making use of an alternating current in

the primary wire. This current flows in a certain direction for 1/120 second. We will try to understand what happens during this one alternation. Before the current from the secondary coil reaches the Leyden jar or condenser, we have a movable spark gap. When the spark gap is closed, equalization of the positive and the negative ends of the secondary

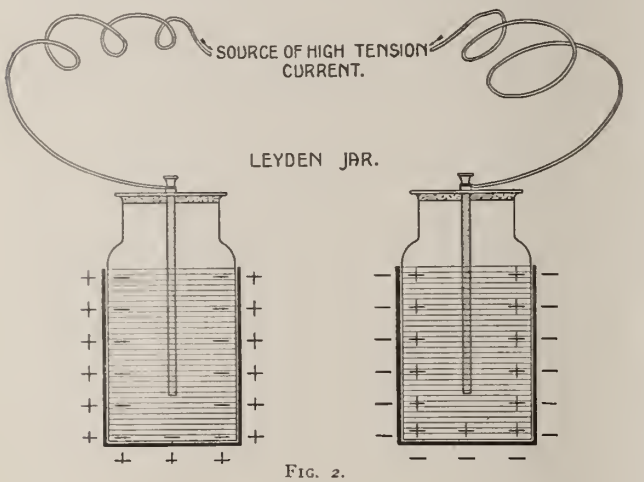

Fig. 2.

coil takes place through this path. Every electric current takes the path of least resistance.

When the spark gap is open never so little, it offers a certain resistance to the current; as a consequence the current spreads all over the inside of the jar until sufficient pressure has been created by the accumulation to overcome the opening or space in the spark gap previously created. The result of this arrangement is that the jar is kept filled with a stress equal to the stress required to break down the distance of the spark gap. The greater the spark gap, the greater the stress in the jar. The spark gap is used as a control. The greater the voltage, the greater the amperage.

To return to the Leyden jars. As soon as the inside capacity of the Leyden jars becomes charged with their respective electricity, say positive, an equal amount of negative stress is induced upon the outside capacity of the same jar. One jar on the inside is electropositive, while the other is electronegative. The inside of the jars is always balanced by the induction of an equal amount of the opposite electricity.

If we take a spiral of a certain size and number of turns of wire and connect the outer sides of the two jars, we have furnished for the jars a path over which equalization can take place. In other words, we have furnished a short circuit. If two wires are attached to the ends of the spiral, or solonoid, as it is termed, the outside capacity of the Leyden jars is thereby increased and some of the current spreads over these two wires.

In the ordinary high frequency machine the patient is placed between the terminals of these two wires. When a patient is so attached, each time that an equalization takes place between the outer coating of the jars the patient shares in this equalization, because he is a part of the outer capacity. Whatever happens to the outer capacity of the jars also happens to the solonoid and the patient. When equalization takes place between the jars, an oscillating current is set up. These oscillations are strongest in their beginning and gradually reach a zero point. To understand these oscillations, let us imagine a steel spring put on tension. As soon as the spring is released it overshoots its mark, and, like a pendulum, gradually comes to rest. There may be from ten to one hundred such oscillations in each equalization.

Bearing in mind that electricity travels at about the same speed as light, which is 186,000 miles a second, we may be able to form an idea as to how many times the inside space of the Leyden jars or condensers can be covered during each alternation of the primary current.

If the inducing current travels 186,000 miles a second, then in 1/120 part of a second it covers 1,550 miles.

If the inside of the jars measures three inches from the centre to the periphery, the space can be covered several million times during each alternation. Since each primary alternation causes at least ten secondary alternations, we may have millions upon millions of alternations a second.

From such figures we see that this current is justly entitled to the title "high frequency."

Most high frequency machines are built upon the foregoing underlying principle. For a long time the profession has been aware of the fact that the voltage or tension in most of the machines was unnecessarily high. The noise from such machines was nerve racking to the patient, and the spark gap could not be kept in order on account of the enormous amount of heat generated in it.

In the Wappler high frequency machine, the current that ordinarily goes to the patient is passed into a primary coil of many windings, which induces a current of lower voltage and higher amperage into a movable secondary with fewer windings. In other words, the current is stepped down from a high tension to a low tension current. The movable coil enables the operator to vary and to control the dose from a current that is hardly perceptible to one of 3,000 milliamperes.

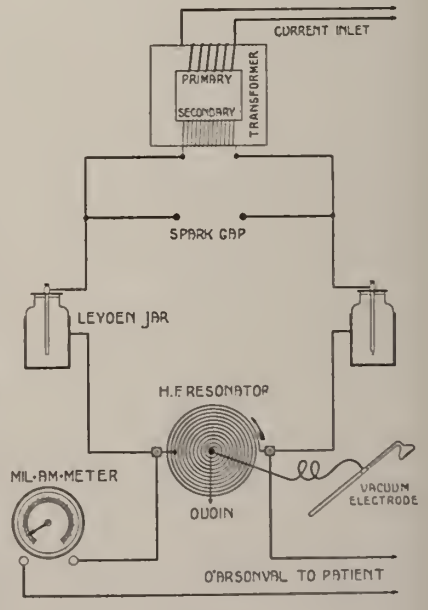

Fig. 3.

When several thousand milliamperes can be passed through a patient with alternations amounting to several millions a second, we have a therapeutic agent in diathermia (heating through) that surpasses all human expectations.

231 West Ninety-sixth Street.

PRIMARY SYPHILIS OF THE RECTUM.

Report of a Case,

By W. E. Jost, M. D.,
St. Louis;
And R. B. H. Gradwohl, M. D.,
St. Louis.

Primary syphilis of the rectum is rare. It is, of course, classified with extragenital chancres. According to Fournier's statistics from 1,124 cases of extragenital chancre we have the following data:

TABLE I. FOURNIER'S STATISTICS.

Cephalic region .. 849	Mouth 729	Lips	567
		Tongue	75
		Tonsils	69
		Gums	11
		Palate	4
		Mucosa of cheek.	1
	Face 119	Chin	54
		Cheek	24
		Eye	21
		Nose	18
		Forehead	2
	Scalp 3		
Upper extremites. 70			
Anus and perineum 78			
Breasts 5			
Trunk 33			
Lower extremities 14			
Cervical region.. 14			

TABLE II. STATISTICS OF E. GAUCHER IN 135 CASES.

Cephalic region .. 98	Mouth 81	Lower lip	30
		Upper lip	21
		Tongue	12
		Tonsils	12
		Labial comissures	3
		Gums	3
		Mucosa of cheek.	1
	Face 16	Chin	10
		Jaw	5
		Forehead	1
	Scalp 1		
Trunk 24	Pubic region 6		
	Anus and perineum 12		
	Breast 6		
Upper extremity.. 8	Forearm 1		
	Arm 7		
Lower extremity.. 5	Inguinal region .. 2		
	Thighs 2		
	Legs 1		

It may be seen from these figures that cephalic chancres constitute perhaps seventy-five per cent. of extragenital chancres. Most of them occur upon the lips, indicating that transmission is by kissing. As for anal chancres, they are observed in women more than in men, usually *a præpostera venere;* in man this is always the case. They are classified as anal, perianal, and rectal. It is to the latter class that the case we report belongs. The perianal chancre resembles a fissure in appearance. The edges are everted and the base is indurated. More than anything we know, its appearance may be compared to an anal fissure that has been cauterized. The anal chancre may be intraanal and may not be seen unless the anal opening is stretched. According to Fournier, it appears as a mere red erosion, composed of two segments which fold upon each other like the leaves of a book. The true rectal chancre, which is very rare, is situated three to four cm. above the sphincter. Bogrow observed one as high up as eight cm. Often it is discovered only in a patient with already pronounced secondaries, where after searching in vain for an initial lesion we are told by the patient that he has had pain upon defecation and that the discharges are colored red from blood. By speculum examination the lesion is then discovered.

It has been noted that there is an accompanying lymphadenopathy in these cases in the external inguinal glands, as was the case with our patient. It must be remembered that inguinal gland enlargement occurs in these cases through the anastomoses between the lymphatics in the concavity of the sacrum and those in the groin. The history of the case is as follows:

Case. The patient was referred to one of us (Jost) by Dr. L. A. Mendoza, on May 3, 1916. He was a French Jew, twenty-nine years old, presenting some characteristics of effeminacy; a waiter by occupation. He complained of a swelling in both groins and a soreness in the rectum. Before coming under our observation he had consulted several other medical men, who had simply ordered local treatment, but had ventured no diagnosis. His rectal trouble had been very annoying to him for about three months prior to the first visit to us. He gave no history of any cutaneous changes before or subsequent to our examination.

Upon rectal examination a well defined lesion was seen upon the anterior wall of the rectum, beginning at the middle part of the sphincter and extending upward. The lesion was single and about the size of a twenty-five cent piece. There was little if any discharge. There was an accompanying bilateral inguinal lymphadenopathy. It might be added that the chancre was fan shaped, as if it were an extension of the mucosa.

Without making any direct examination of the lesion for spirochetes, the blood was examined, resulting in a strongly positive Wassermann and Hecht-Weinberg-Gradwohl test. The patient, upon hearing our opinion of his case, confessed that he had exposed himself to the sexual attack of a sodomist.

An immediate injection of arsenobenzol was given, and within two days the lesion began to disappear rapidly and fade in color. On the fourth day the lesion had completely healed and the tissue covering it had taken on the appearance of the surrounding mucosa.

928 North Grand Avenue.

THE ORAL ADMINISTRATION OF ADRENALINE.

By Henry R. Harrower, M. D., F. R. S. M. (Lond.),
Los Angeles, Cal.

The active chemical entity prepared from the adrenal medulla is oxidized and destroyed very easily in the body. This accounts for the ephemeral effects which follow its administration as a remedy; and also the comparative rarity of the symptom complex of hyperadrenia. *In vitro* adrenaline is quickly destroyed by numerous reagents and it has also been shown experimentally to lose its activity when in contact for a short time with an artificial gastric juice under conditions as nearly similar as possible to those in the stomach. If adrenaline is given by mouth, and the stomach is evacuated ten minutes later, it is usually impossible to detect this substance by colorimetric chemical measures. In the fasting stomach this disintegration is accomplished in almost the same time, though here the writer is by no means sure that this really means that the adrenaline is destroyed, for some of it is absorbed.

All these technical experiences have led to a quite natural impression that adrenaline was not effective when given by mouth, and that to obtain other than the well known results, it must be given by hypodermic or intravenous injection. There are not a

few references in medical literature, including that of the manufacturers, which indicate that this idea is well grounded in the minds of the profession.

For years I have been convinced by personal experiences that this opinion was misleading, and am confident that unquestioned therapeutic effects have followed the oral administration of adrenaline.

In a short communication to the editors of the New York Medical Journal (July 8, 1916, p. 94) Leland Boogher relates some interesting personal experiences following the use of fifteen minims of adrenaline solution (presumably the standard one in 1,000 solution) in a tablespoonful of water by mouth for the relief of excruciating abdominal pain due to an abscess in the transverse colon. Boogher has since recommended this measure as an analgesic remedy for gallstone and renal colic, and "it gave splendid relief." This reference emphasizes what is probably an original application of this much used remedy; and credit for this should be given to Dr. George Richter, of St. Louis, who prescribed the treatment outlined above.

However, this experience is also corroborative evidence of a well established fact, still denied in many quarters, that adrenaline *per os* is both potent and useful. In *American Medicine* a number of items have been reported which substantiate this view. In the issue for April, 1915 (p. 253), there appears an article entitled Giving Organotherapeutic Products by Mouth, in which reference is made to the prevalent but mistaken notion as to the availability of many organotherapeutic extracts when given *per os*. Reference was there made to a statement to the effect that "these (organotherapeutic) extracts, with the possible exception of thyroid, are destroyed in the stomach; hence it is useless to give them unless hypodermically." The writer then proceeded in the following terms: "This is not true, and the statement can be easily disproved. . . . Why, if organotherapeutic remedies generally are destroyed by the digestive juices, should thyroid be the lone exception to the rule? Wherein does the active principle of the thyroid differ in its absorbability or destructibility from the hormones of the adrenals, pituitary, or gonads? The most conclusive and practical proof of the inaccuracy of such a position would be to have those who make such statements (or believe them) take, say, an ounce of one in 1,000 adrenaline chloride solution—it contains less than half a grain of the adrenal active principle —and note carefully if there is not a considerable modification of the circulatory equilibrium!"

Several of the statements as to the destructibility of adrenaline when given by mouth appear in the publications of the American Medical Association, though, curiously enough, in the weekly department on Therapeutics in the *Journal A. M. A.* (October 16, 1915, p. 1366) there is a brief consideration of the emergency treatment of sudden cardiac failure from which the following statement is cited: "Epinephrine may be given in a dose of five drops on the tongue, which may be repeated in half an hour if advisable. . . . All of the foregoing (including strychnine, hot coffee, camphor, etc.) are quick acting treatments." This casual statement is of unusual interest, since the use of epinephrine (which, by the way, is not obtainable on prescription, as there is no such preparation on the market, but is presumably intended to mean adrenaline) is advised to be given by the mouth, contradicting statements in the *Journal A. M. A.* and elsewhere which indicate that this drug is useless given in this manner; and here, be it noted, this remedy, in a dose of only five drops on the tongue, is classed as a "quick acting" cardiac stimulant.

There are a number of other references to the effective administration of adrenaline by mouth, a few of which will be referred to shortly. It should be understood, however, that such fundamental errors as the one under discussion are due to the drawing of conclusions from laboratory experiments alone. We grant that adrenaline is "digested" in the test tube. It is easy to prove that it cannot be recovered from the gastric contents after being in the stomach for only a short time. None will deny that it is rapidly and thoroughly oxidized. But adrenaline is also very easily absorbed, as every rhinologist knows and as any physician can quickly find out if he cares to hold a dram or two in his mouth for a few minutes. Is it not possible, then, as the writer suggests, that the factor of destruction in the stomach is not concerned at all, but that much or all of the active principle is taken up by the mucous membrane of the mouth, palate, esophagus, and cardia, thus enabling it to exert its therapeutic effects and to maintain its reputation as a "quick acting" remedy when given by mouth?

In connection herewith it should be recalled that the administration of hormones—and adrenaline is certainly a hormone and has been quite properly called the "chromaffin hormone"—brings about physiological effects in two ways: First, by the direct action of that part of the actual substance administered; and, second, by the increased production by the organism of the hormone corresponding to that which is given. In other words, when we give adrenaline, not only do we get the direct drug effect from the dose which is absorbed, but at the same time we are increasing the capacity of the adrenal medulla to produce more of its chromaffin hormone This important principle of organotherapy is embodied in Hallion's law of homostimulation: "Extracts of an organ exert on the same organ an exciting influence which lasts for a longer or shorter time. When the organ is insufficient it is conceivable that this influence augments its action, and when it is injured that it favors its restoration."

We know, from many experiences with thyroid therapy, that with a presumably normal or even a slightly deficient thyroid, certain doses of thyroid extract will bring about symptoms of hyperthyroidism the results of which are not directly due to the drug administered, but to the increased thyroid activity, and these results remain long after the comparatively small amounts of thyroid which were given have been used up. This shows that the principle of homostimulation applies to normal as well as disordered glands, and this is by no means impossible with the adrenals as well as with the thyroid.

To lend emphasis to the position taken by the writer, as well as to Boogher's brief but interesting communication, a few clinical reports from recent literature may advantageously be collated here:

Hutinel (*Arch. de méd. des enfants*, February

and March, 1915) recommends three or four drops of adrenaline one in 1,000, diluted, every two or three hours, as a part of the treatment of severe infectious diseases in children. Each child may receive as much as twenty minims a day by mouth, and Hutinel remarks that he has never obtained so much benefit from the usual supporting measures and that the effects are remarkable even in the gravest cases, since the blood pressure is increased and there is an immediate response in the general mental and physical condition, while the pulse rate is reduced and diuresis is favored.

M. H. Smith (*Medical Record*, October 2, 1915, p. 586) reports having successfully treated several cases of Rocky Mountain spotted fever with ten drop doses of adrenaline solution every four hours This obviated the prostration common in these cases, convalescence was established earlier than usual, and there was an apparent beneficial effect upon the course of the disease. That the remedy given by mouth was "quick acting" is emphasized by Smith's remark that within a few minutes of the administration of each dose, a fullness of the pulse and a fading of the eruption were noticeable.

Not much has been done in this country with the use of adrenaline for the treatment of nephritis, though at least five articles have appeared in current Italian medical literature speaking well of this method. The most recent reference is abstracted in the *Journal A. M. A.*, June 10, 1916. This abstract from *Il Policlinico* (April 30, 1916) may be cited in full: "Borelli reports two cases of acute and one of chronic nephritis in which remarkable benefit was realized by epinephrine[1] treatment. One patient was a child of nearly five years, the others were men of fifty and sixty-two. He gave the child sixteen drops a day of a one in 1,000 solution of epinephrine, four drops at four hour intervals. The adults were given forty drops a day, eight at a time. Ercolani called attention, in 1910. to the benefit from epinephrine by the mouth in nephritis, commending the harmlessness, ease, and efficacy of this method of treating kidney disease, which has proved its usefulness again and again, and Borelli's experience has confirmed his statements."

Previous to this report another exhaustive study on the subject was published by Silvestri (*Gaz. d. osp. e d. clin.*, September 1, 1915), in which he analyzes the reports of a number of other clinicians, adds several personal experiences, and proves that adrenaline is a most valuable aid in the acute stages of nephritis, but of little value in chronic conditions. He also tells of the experiences of Fede, who found this procedure comparatively more effective in children, since in them the elasticity of the renal glomeruli and tubules is greater, while the adrenal glands are proportionally larger in children than in adults (presumably being more susceptible—quantitatively—to the homostimulant action referred to previously). Silvestri suggests that one or two minims of the one in 1,000 solution of adrenaline chloride be dropped on the tongue every three hours—the total amount given *per diem* being regulated by the clinical response of the patient. For adults the dose may be larger.

There are also numerous reports in the literature of the therapeutic efficacy of total adrenal gland, and of course this is given *per os* in tablet form. In a recent monograph on the Drug Therapy of Cardiovascular Diseases, Satterthwaite (*Int. Clinics*, I, 1916, page 26) recommends desiccated adrenal gland as a useful vasomotor tonic in doses of two and a half grains three times a day, and remarks that single doses as a rule will relieve palpitation in a comparatively short time. The active principle of the desiccated gland is naturally similar to that which is available in a pure state, and the favorable experiences with total adrenal gland therapy, by mouth of course, is additional proof that the position of those who have contended that the oral administration of adrenaline is useless, is fallacious.

715 Baker-Detwiler Building.

[1] "Epinephrin" is the term used uniformly in all the publications of the American Medical Association, although in this instance the title of Borelli's original article is as follows: "Cura della nefrite con la soluzione di *adrenalina* nella pratica di condotta."

ANESTHESIA REVIEWED.

By James T. Gwathmey, M. D.,
New York.

(*Continued from page 830.*)

NITROUS OXIDE.

Nitrous oxide gas (Bevan).	*Nitrous oxide and oxygen (Gwathmey).*
1. Safety.	
Gas for short anesthesia, such as pulling teeth, opening abscesses, etc., is the safest anesthetic known. In prolonged anesthesia, a half hour or more, gas is now known to be more dangerous than ether. I refer now to the use of gas and ether in the hands of experts. In nonexpert hands, gas in prolonged anesthesia is much more dangerous than ether.	Gas should never be used alone, as it is unsafe even in *short* operations. Some surgeons in opening abscesses, and some dentists in extracting teeth, have become so accustomed to asphyxiating their patients, removing the mask and then operating, that the words "asphyxia" and "anesthesia" are synonymous with many of them. As asphyxia is the principal danger with this anesthetic, and as oxygen in a measure removes this danger, it should always be used in combination. But even in combination it is safe in *some* cases and dangerous in others. The *longer* the operation the *easier* and *safer* it becomes to maintain anesthesia.
2. Comfort.	
Gas affords the most agreeable inhalation anesthesia.	With oxygen, a most agreeable anesthetic.
3. Relaxation.	
Gas is not an efficient anesthetic, such as chloroform or ether. Complete anesthesia and complete relaxation for prolonged periods are difficult to maintain, and are not possible in a considerable proportion of cases.	With proper preliminary medication, complete relaxation for prolonged periods is easily maintained.
4. Control.	
Gas can at once be stopped at danger signals, and the agent already in the system is rapidly eliminated, more rapidly than any other agent.	If patient is asphyxiated, removal of mask alone will remedy that trouble. If a weak heart becomes dilated, the issue is doubtful.

5. Simplicity.

The apparatus for giving gas is not very complicated, more so, however, than that used in giving ether and chloroform. It is not so widely adaptable as ether. The apparatus is heavy and cumbersome, and somewhat difficult to transport. This objection can be overcome.

Apparatus is less complicated and lighter than that used in giving ether or chloroform.

6. Aftereffects on Blood, Tissues, and Viscera.

Aftereffects on blood tissues, and viscera, practically negative.

Same.

7. Complications.

Vomiting occurs in but a small proportion of cases.

Same.

8. Effects on Immunity.

It has little or no influence on immunity.

Same.

Conclusions.

Gas should be one of the general anesthetics employed in the surgical clinic. Its place should be for short anesthesias in which unconsciousness is desired and local anesthesia is not applicable—in reducing fractures and dislocations, opening abscesses, and in some more prolonged operations in which for special reasons gas becomes safer than ether, such as operations on the urinary organs with kidney insufficiency. A surgical clinic which does not frequently employ gas anesthesia is, from the standpoint of anesthetics, a poorly conducted clinic.

As ninety per cent. of the deaths with this anesthetic, as with all others, occur in the first few minutes, it should never be used in short operations, except by an expert. Nitrous oxide and oxygen will be used less as a routine method as the profession becomes more thoroughly acquainted with the fundamental principles underlying the proper administration of ether and chloroform.

INTRAVENOUS ANESTHESIA WITH ETHER.

1. Safety.

Both clinical and laboratory work shows that it is a dangerous method. Clairmont and Denk, after careful experiments on dogs, have concluded that it is too dangerous to employ in clinical work. Kuttner has two cases of lung embolism in twenty-three cases.

Like all others, when thoroughly understood, this is a perfectly safe procedure.

2. Comfort.

It is an agreeable anesthetic, as it does away with the disagreeable odor and irritation of inhalation of ether.

Same.

3. Efficiency.

It is efficient, but the border line between anesthesia and a toxic dose is too narrow.

Efficient; border line between anesthesia and toxicity, wide.

4. Control.

When once injected into the circulation, it is beyond immediate control.

Under control at all times.

5. Simplicity.

The apparatus and technic are complicated and require special watchfulness. It could not be generally adopted.

Apparatus and technic simple, and admit of general adaptability.

6. Aftereffects on Blood, Tissues, and Viscera.

Aftereffects are much the same as in the case of ether inhalation.

Compared to the open drop, the aftereffects are entirely in favor of intravenous anesthesia.

7. Complications.

Complications are the same as with ether inhalation.

Infection and embolus are the only dangers. The usual complications of drop ether inhalation are unknown.

8. Effects on Immunity.

Effect on immunity is the same as with ether inhalation.

A more favorable effect than with inhalation ether.

Conclusions.

Too dangerous, too complicated, no special advantages, should be rejected.

This method gives a beautiful anesthesia when the technic of Honan and Hassler(13) is followed. The danger of infection, embolus, and thrombus must always be considered. "The employment of ether in this way seems almost devoid of danger from either immediate or remote complications."

COLONIC ANESTHESIA.

Intrarectal anesthesia (Bevan).

(This is an old method introduced as early as 1847, and revived from time to time.)

Oil ether colonic anesthesia (Gwathmey).

(Introduced in 1913.)

1. Safety.

It is not a safe anesthetic.

It is a *perfectly safe* anesthetic.

2. Comfort.

It is not a comfortable method of taking ether.

It has been given to hundreds of patients without their knowing that they were getting an anesthetic.

3. Efficiency.

It is not very efficient.

Entirely efficient.

4. Control.

Much the same as with intravenous anesthesia.

The anesthetist has perfect control of the anesthesia all of the time. It can be lightened or deepened when needed, or concluded when necessary.

5. Simplicity.

The method is complicated, and cannot be generally adopted.

The apparatus required consists of two rectal tubes and a funnel. The technic is as simple as the apparatus. Admits of universal use.

6. Aftereffects on Blood, Tissues, and Viscera.

Aftereffects on blood and tissue same as inhalation anesthesia.

Tissues of colon and lungs not affected, as is tissue of lung with inhalation anesthesia.

7. Complications.

Distention of bowels, very severe, local irritation of colon, with colicky pains and bloody diarrhea, often fatal.

Colicky pains are rare, no local irritation or bloody diarrhea in over 2,000 cases.

8. Effects on Immunity.

Effect on immunity same as in ether inhalation.

The general effect is about the same as with warmed ether vapor inhalation, with the *notable exception* that *gas pains are rare.*

Conclusions.

Rectal anesthesia should be rejected.

Oil ether rectal anesthesia will be used more and more as the fundamental principles upon which it is based are known. When properly used in conjunction with local anesthesia, or with blocking or infiltration anesthesia, these latter methods are greatly increased in value.

Endotracheal[1] *anesthesia.* (*Bevan*). (This interesting method, introduced by Meltzer and Auer, has not yet been used in a very large series of cases.)	*Endotracheal*[1] *anesthesia*
1. Safety.	
Robinson collected 1,400 cases with seven deaths, one from lung rupture and one from emphysema.	A few deaths were reported upon the introduction of this method. These deaths were avoidable. Judging from the *large number* of successful cases at Mount Sinai and Roosevelt Hospitals, and at other clinics, this seems to be a safe method. In the writer's opinion it should not be used except when positive pressure is needed.
2. Comfort.	
The same as drop ether which precedes the intubation.	The same as the nitrous oxide-oxygen-ether sequence, which usually precedes it. *Drop ether* takes longer and does not produce the *deep*, safe anesthesia necessary for the introduction of a catheter, and should therefore *never* be used.
3. Efficiency.	
It is an efficient method.	Entirely efficient.
4. Control.	
The same as with drop ether.	A better control than drop ether.
5. Simplicity.	
It requires a complicated apparatus. It requires, first, anesthesia by drop ether and then a change to intubation. It could not be generally adopted.	The "apparatus" is much simpler than the automobile engine, now universally used.
6. Aftereffects on Blood, Tissues, and Viscera.	
Aftereffects same as drop ether.	Aftereffects are much better than drop ether, unless this method has been used as a preliminary.
7. Complications.	
Complications same as drop ether.	Complications unlooked for, unless a poor preliminary anesthetic has been used.
8. Effects on Immunity.	
Effect on immunity same as drop ether.	Resistance is not impaired as much as when drop ether is used.
Conclusions.	
The method is dangerous. It is complicated and it possesses advantages in very few cases. When it was introduced it was welcomed as a simple method which had all the advantages of the complicated differential pressure methods which had been experimented with in thoracic surgery. As a matter of fact, both the complicated differential pressure and the intratracheal methods have practically been largely eliminated as a result of further investigations in thoracic surgery, which have demonstrated the fact that most of the operable cases in thoracic surgery can be done either under local anesthesia or drop ether or gas and oxygen; that the necessity of preventing collapse of the lung when but one pleural cavity is opened was theoretical and not real, and lastly, by the fact that the extensive work in which both pleural cavities are involved and such extensive work as attacking the thoracic part of the esophagus cannot as yet be accepted as warrantable surgical procedures; furthermore, the introduction of the simpler method of intrapharyngeal anesthesia has eliminated the intratracheal method from the field of head surgery, in which for a time it seemed to have a place. On the whole, therefore, intratracheal anesthesia has little place in practical surgery.	The method is now perfectly safe. It will fall into disuse because endopharyngeal anesthesia accomplishes practically the same results without loss of time for insertion of tube. Furthermore, the ether vapor mask (a semiclosed method) is a better procedure than the endopharyngeal.
Endopharyngeal Anesthesia (*Bevan*). (This is an old method introduced years ago and reintroduced from time to time with changes in apparatus. The special advantage is that in mouth and jaw work after the patient has been anesthetized by drop ether, the mask can be removed, the catheter introduced into the pharynx through the nose or mouth and anesthesia continued without interfering with the operative field).	*Endopharyngeal Anesthesia* (*Connell*). (This method was popularized and placed upon a scientific and successful basis in our own time by Karl Connell, of Roosevelt Hospital. It should be used instead of the endotracheal.)
1. Safety.	
It is about as safe as drop ether.	It is much safer than the drop ether method, as a glance at the chart will show.
2. Comfort.	
The same as drop ether, which it succeeds.	It is usually preceded by the gas-ether sequence, but preferably the gas oxygen ether sequence. A quicker, *safer* anesthesia is thus induced, with *all reflexes* abolished, and should be used in preference to the open drop method. This sequence is the usual procedure in New York.
3. Efficiency.	
Not quite as efficient as drop ether, but nearly so.	More efficient than the drop ether, when proper preliminary medication is used.
4. Control.	
Same as with drop ether.	A more even plane of anesthesia is maintained than is ever possible with drop ether. Patients come out of this anesthesia in much better condition than with the drop method.

[1]The Greek prefix *endo* is preferable for use with "trachea" and "pharynx," both Greek derivatives, rather than *intra*, which is a Latin prefix. It is also more euphonious.

5. Simplicity.

It can be operated with a hand bellows, but better by an electric pump, if this is kept up in perfect working shape. It can be fairly generally adopted for use in mouth and jaw work.	Compares favorably with all other forms of ether anesthesia.

6, 7, and 8.

Aftereffects, complications, and effects on immunity same as drop ether.	Aftereffects, complications, and effects on immunity *much less* than with the drop method of ether. Both clinical and laboratory experiments seem to bear out this statement.

MIXTURES AND SEQUENCES.

As already stated, if safety is the first consideration, mixtures and sequences of anesthetics will be used more and more. This seems borne out in part by the work in the laboratory already referred to, and also by statistics. The reader is respectfully referred to an article, Nihilism in Drugs, by Dr. Abraham Jacobi (14), in which he states: "The word polypharmacy contains a reproach to which nobody will submit"; and also, "by the purists among us polypharmacy is called even the prescribing of more than one medicine at one time. . . . There is no ground for the pedantic demand that two medicines with similar action should not be prescribed together." We are not, therefore, disturbed by the reproachful phrase of "shotgun" prescriptions. If, as many physiologists hold, different anesthetics and narcotics affect different parts of the central nervous system, why should not preliminary medication combinations, sequences, and mixtures be used instead of some one drug or anesthetic?

GENERAL CONCLUSIONS.

1. The "drop method of ether" has won unusual and unmerited favor within the past few years, entirely on account of its advocacy by certain eminent surgeons. Its bid for popularity is not on scientific grounds, but on account of the simplicity of administration, and its supposed safety. It should be discontinued for simpler and safer methods. Those wedded to ether by the open drop method, and who have good results and statistics, will get better results and statistics by using ether administered as described. Any anesthetist who can give the open drop ether can readily acquire facility with the *vapor method*.

2. Oil-ether colonic anesthesia should be used whenever the anesthetist is in the way, or whenever the element of fear dominates the patient. The obese alcoholic, who takes kindly to no form of inhalation anesthetic, is the best subject for this special agent.

3. "Gas" should never be used alone. Nitrous oxide and oxygen should take its place.

4. *Preliminary medication of some kind should be used in all surgical cases unless contraindicated.*

5. Sequences, combinations, oxygen, warmth (about 98° F.) are additional factors of safety in the administration of nitrous oxide, ether, ethyl chloride, and chloroform.

6. Anesthesia, like other branches of medicine, is still in an evolutionary state. It is, therefore, wrong to attempt to settle upon any anesthetic or method at this time. The subject should be approached with a free mind. Advice should be withheld unless reinforced by laboratory and clinical facts.

Believing absolutely in the sincerity of purpose of those who advocate the plan of one method for all cases, I am, nevertheless, so convinced of the greater wisdom of suiting the agent and the method to the patient and the procedure that I would be glad of the opportunity of convincing those of the opposing view. *I should be glad, for instance, to demonstrate in any clinic that warmed ether vapor with oxygen is as good from every viewpoint as nitrous oxide and oxygen. I shall willingly demonstrate that modern methods of ether administration are superior in every way to the drop method of ether.*

TRACHEOBRONCHITIS DUE TO NITRIC ACID FUMES.

Bronchoscopy; Drowning of the Patient in his Own Secretions Averted by Tracheotomy,

By Chevalier Jackson, M. D.,
New York.

Case. David E., aged thirty-five years, pipe fitter by occupation, previously in good health, was admitted to Allegheny General Hospital, complaining of burning in the throat following a two hours' exposure to nitric acid fumes. Half an hour after exposure, his lips became blue. Five hours later, patient fell, becoming unconscious for a few minutes. Then cough, difficulty in breathing, and blueness of lips and face were noticed.

Physical examination (Dr. J. P. McKelvy): Sibilant and subcrepitant rales all over both lungs anteriorly and posteriorly. Fine moist rales heard in axilla. In left axilla and in front inspiration markedly increased. Whispered voice plus. Showers of fine crepitant rales were audible at end of inspiration.

Indirect laryngoscopy. Frothy mucopus could be seen bubbling up and down in the trachea, which seemed full of secretion; but there was no coughing effort to expel them and no glottic bechic placement.

Bronchoscopy showed intense acute tracheitis and bronchitis; the trachea and bronchi were full of frothy mucopurulent secretion. On wiping this away, patches of grayish furred mucosa, with a surrounding areola of intensely engorged cyanotic mucosa, were seen in the trachea and right bronchus.

The patient was cyanotic and at times unconscious. He was choked with his own secretions until he was apparently drowning. Tracheotomy was therefore advised.

Tracheotomy was done by Dr. Walter Dearth and a large full curved Jackson tube inserted, through which large quantities of tenacious frothy mucopus were continuously removed. The temperature, which on admission was 101.3° F., never rose above 102° and subsided to normal at the end of a week. The air passages were cleared by gentle swabbing through the tracheotomy wound. The cyanosis disappeared as the secretions were got rid of. At the end of the fourth day, the patient could cough out the secretions through the cannula. The windows were kept open, and compound tincture of benzoin was vaporized from a croup kettle close to

the cannula. Atropine and stimulants were given as needed. The symptoms gradually subsided, and the patient was discharged well at the end of three weeks.

REMARKS.

In view of this and similar cases it would seem that when the physical signs as here noted by Dr. J. P. McKelvy, taken together with the laryngoscopic findings and the absence of cough reflex, all point to the drowning of the patient in his own secretions, tracheotomy should be done in order to give easy access to the lower air passages for the frequent removal of secretions, provided that the basic condition is curable. Manifestly the procedure is not indicated in patients filling up in process of dying of a necessarily fatal illness, such as thoracic cancer, aneurysm, etc., as previously reported.[1] While possibly the frothy, tenacious mucopus could have been removed by repeated bronchoscopies; yet in the acutely inflamed condition of the mucosa bronchoscopy three or four times daily seemed less desirable than tracheotomy. The cause of the feebleness and inefficiency of coughing effort is difficult to explain; possibly it was toxemia or shock.

40 East Forty-first Street.

[1] *Laryngoscope.*

MALOCCLUSION OF THE TEETH.

Its Pathological Effects,

By Henry C. Ferris, D. D. S.,
New York.

A review of recent pathology discloses a tendency to neglect or to minimize the importance of the oral cavity. The oral cavity should be considered an organ of the human body. With thirty-two teeth of the highest organized physical structure operated by eight pairs of muscles with power only second to those of the heart, with forty-eight ounces of secretion daily, having an enzymic value and a reflex action upon the primary gastric secretion, it compares well with any other organ.

The abnormal locking or malocclusion of the inclined planes of the teeth in this organ are considered the result, rather than an etiological factor in pathological states; but a careful consideration of the relation of the human teeth to the growing organism from the tenth week of fetal life to maturity will greatly modify the accepted pathological theories.

"The Babylonians located the brain in the liver; and it was not until the discovery of the physician, Galen, about A. D. 160, that the brain was acknowledged to be the seat of thought and feeling (Thompson)."

May it not be that scientists in their search for knowledge of the maladies that our system is heir to, guided perhaps by a desire to relieve acute painful conditions, have neglected to study the portal of the alimentary canal, because of its easy access and its supposedly simple anatomical and physiological mechanism? Frequently diseases which are regarded as deep seated and serious, are found to be only symptoms of very simple cause, which the ortho dontist locates in the patient's mouth.

Biologists examining saliva have encountered problems worthy of their best study; but so far they have not been able to analyze completely the properties of this secretion. That it contains three ferments and a specialized mucus is sufficient for our present consideration.

This secretion, as shown by Professor Pavloff in his most recent investigation of the secretory glands, is stimulated and specialized by the sense of taste, and controlled by psychic influences from the optic, olfactory, and auditory nerves. Clinical experience has taught the dental surgeon that the services he performs improve the general health of his patients. Dental surgery, therefore, is only a highly specialized form of medical practice, and its field is in one of the most important organs.

The pathologist may take good care of his own teeth, but he pays little attention to the teeth of his patients when studying etiology. The reason for this neglect may be properly credited to the dental surgeon, whose attention has been largely centred on the mechanical restoration of the teeth lost through caries. Moreover, as an association we may be to blame because so few of the records of the physiological benefits derived from our labor have been reported, and not all oral specialists themselves are fully informed as to the influence our region exerts upon the whole organism.

It is rightfully contended that man can live without teeth by natural selection of his food, but these cases are comparatively few, without accompanying pathological conditions. A visit to our hospitals and insane asylums would establish the truth of this assertion. We may exist without one kidney, or with an artificial fistula in the stomach. These cases are rare; but literally thousands are suffering from diseases which slowly and surely are destroying their systems as a result of loss of function of the organ of mastication.

The United States Government does not accept men in army or navy who do not have at least four molar teeth in contact, because statistics have shown that men without molars spend a large portion of their time in hospitals, and become a charge upon the government.

This rule has been adopted after years of experience and tabulated reports; and may be due to a mechanical locking of the inclined planes of the teeth. When in normal occlusion, thirty-two teeth have 206 inclined planes of their cusps in contact, and assuming this as representing 100 per cent., we may calculate the mechanical functioning ability of this organ. The loss of three first molars decreases the organ to seventy-four per cent. of its normal ability to reduce the carbohydrate food, as the tongue selects these teeth to perform that function.

In Class I (Edward H. Angle's classification) the molars are in occlusion, but the premolars and the incisors (patterned after the carnivora) are in malocclusion. These teeth are involuntarily selected by the tongue to reduce meat and proteid food.

In Class II, Division I, we have both classes of teeth in malocclusion. As in Class III, owing to the abnormal relation of the mandible to the head, we find the angle of contraction of the muscles altered,

which results in reducing the power; thus minimizing the normal mechanism of the organ.

An analysis of the feces of seventy-five patients before and after the restoration of missing teeth, is reported by Professor A. Michels, of Würzburg, Germany, in the transactions of the Odontological Society of Frankfurt, to show the value of the function of the molar and premolars upon digestion.

Acknowledging that these abnormalities do reduce the function of this organ, what effect has this condition upon the pathological condition? In order to study this subject in the space allotted, we shall divide malocclusion into three classes:

1. Malocclusion due to congenital or hereditary tendencies.

2. Malocclusion where the child is normally born and the developmental forces are interfered with after birth by infectious disease, traumatic injury, etc.

3. Malocclusion due to the loss of function of the organ owing to environment, dietetic habit, or mutilation of the arches by extraction.

We shall consider only the latter class, dividing it again into primary and secondary. We assume that all are familiar with the effect upon the anatomy of the head as influenced by the loss of function in the growing child.

First, a loss of function lateral or bilateral, resulting in an underdevelopment of the bones of the head as proved by the experiments of Dr. Lawrence Baker, of Boston, Mass. On account of this lack of development, we produce mouth breathing, and disturbances of the respiratory system. This interference with nasal breathing results in abnormal development of the nasal bones and tissues, producing curvature of the vomer, adenoids, polypi, etc.

The circulatory system is affected as a result of insufficient oxidation of the blood, owing to a contracted thorax in this class of cases, voluntarily reducing the lung capacity in an effort to overcome thermal shocks to the lung tissues. It is rightfully said "we may live forty days without food, three days without water, but only three minutes without air." Premature extraction of the deciduous teeth may prevent normal nasal breathing by reducing the diameter of the anterior nares.

DIGESTION.

The digestion of carbohydrates is reduced in varying degrees. A patient with a twenty per cent. efficiency has to chew fifty times to accomplish the same reduction. Whoever bolts his bread overtaxes the powers of gastric and intestinal digestion, and diseases of the stomach and intestines result.

"It is true that in laboratory experiments with test tubes the pancreatic secretion has a stronger and more complete hydrolytic action upon the digestion of starch than saliva, but if salivary digestion of mankind does not act normally upon starch, the pancreatic secretion is never sufficient to digest this material. The undigested starch that remains partly ferments and is accountable for pathological states such as cardialgia, duodenal catarrh, and fermentative lientery with air bubbles." (Felix von Oefele.)

This undigested starch fermenting in the intestines produces lactic and acetic acids, and establishes acidosis, autointoxication, and a chronic irritation to the kidney and urinary organs, with its accompanying maladies. A vicious circle is established, showing high acidity in the salivary secretion as in urine. A coefficient of the undigested food is greatly increased, while the index of autointoxication is decreased. These findings are sufficiently pernicious to be considered primary etiological factors in most any disease of the body.

NERVOUS SYSTEM.

The nervous system is influenced by the lesions produced in the stomach and intestinal tract; and because of the loss of development of the bones of the head and face, small orbits, small foramens, and small antra for the type result. It is beyond our power to analyze the effects of the underdeveloped brain box as a result of loss of function of the masticatory muscles of the growing child; but in view of the present surgical operations upon the skull and the marvelous effects of trephining upon the general nervous system we must pause before discrediting the possibility of depressed function of a brain in an osseous cavity smaller than the architectural plan for any individual type.

Infantile forms of epilepsy are influenced, if not entirely cured, by the return of the teeth to their normal position. I have had two patients, one in a medical man's family and one under the observation of a medical attendant. Both patients had fifty attacks a year, but after two months of teeth movement, with the expansion of the superior arch, the attacks entirely disappeared.

Radiographic records of Class III cases frequently show an enlargement of the pituitary body, and the mental balance is markedly influenced in Class II, Division 1, cases, while the scholastic ability is immediately improved after correction in this class.

REPRESSIVE TISSUE CHANGES.

Such changes are marked locally, first in atrophy of the alveolus. Caries is increased, owing primarily to the accumulative spaces between the teeth and the inability of the tongue and cheek muscles and the lowered physiological value of the saliva to cleanse the surfaces; secondly through lowered vitality of the system, reducing the blood pressure to the teeth and rendering them more susceptible to caries; and the metabolism of the tissues is disturbed by insufficient nourishment.

PROGRESSIVE TISSUE CHANGES.

In Class III we find an enlargement of the body of the mandible and accompanying hypertrophied tonsils, and in most cases of acromegaly the upper arch is mutilated by extraction of teeth and malocclusion is progressive.

INFLAMMATION.

Locally, in mutilated cases, we find teeth loosening; pyorrhœa alveolaris, stomatitis ulcerosa, papilloma, carcinoma of the tongue and mucosa, ulcers of the stomach and duodenum are not uncommon, and the urinary organs have their share of irritation in acidosis.

PLANT PARASITES.

The mouth breather dries the mucous membrane, reducing the natural protection of the secretion to tissue and tonsil, carrying large quantities of bac-

teria to the lungs, increasing their liability to infection from this source. These patients are susceptible to phthisis, pneumonia, diphtheria, and follicular tonsillitis. The tonsils become impaired, permit of streptococcic infection, resulting in heart and stomach lesions, and we seldom see patients with a Class II, Division I, over forty-five years of age, in spite of their large numbers in youth. They have passed to another world.

MALFORMATION.

As previously stated the spine is curved, ribs are underdeveloped, rickets, clubfoot, and knockknee, disturbed metabolism, and bone diseases of the head and face follow. It is said that all specialists can trace diseases to their own region of activity, and some may take issue with many of the statements made in this paper, but show me the case of chronic lesion in the body, and I will show you a defective month, or if perchance the occlusion is normal, I will prove with a series of pills of a given diameter that the subject is a "bolter" of his food and neglects the function of mastication. This function is largely voluntary and, therefore, much more difficult for the specialist to control than any other.

This paper deals with only one class of patients, but I have treated the congenitally defective and greatly improved their hearing, eyesight, digestion, and metabolism, and caused them to develop where the chances of life were small.

This subject is in its infancy, and as we learn to trace the etiology of diseases, pathologists themselves will, in due time, come to appreciate the value of thirty-two teeth in normal occlusion. If this attention is not given, they must look to their laurels, for many pathological conditions yield to normal functions of the organ of mastication without medication.

AUTOTHERAPY IN IVY POISONING.

By Charles H. Duncan, M.D.,
New York.

In the New York Medical Journal for September 2, 1916, was an editorial article reviewing an article by Dr. J. M. French that appeared in the August, 1916, issue of *Clinical Medicine*, in which the writer stated that ivy poisoning may be cured or prevented by chewing the young leaves of the plant and swallowing the juice. The writer acquiesces in every respect with the editorial comment on this method of treating ivy poisoning which was as follows: "The remedy appears to be in accord with the theory and practice of Dr. Charles H. Duncan, who will pounce upon this case report as a fine example of his beloved autotherapy."

In the New York Medical Journal for December 14 and 21, 1912, the writer stated in an article under the title of Autotherapy: "Disease may be said to be the proving of one or more toxins. Symptoms are the expression, or the language, of toxins. *The cure of disease is brought about by placing the exact toxins that cause the symptoms in healthy tissues.*" This method of treating ivy poisoning is nothing more or less than treating the symptoms with the substance that caused them, or an autotherapeutic procedure, and has long been known and employed successfully by the writer, as in other forms of anaphylaxis.

In Fairmount Park, Philadelphia, it was the custom a few years ago upon hiring park hands, to instruct them, upon clearing away poison ivy, to chew a few leaves of the plant as a preventive to the well known cutaneous eruption. Last spring, this autotherapeutic method of preventing ivy poisoning was introduced in Bronx Park, and several of the workmen employed it as a prophylactic. It is noteworthy that no one who chewed the leaves suffered afterward from poisoning.

Case. C. V., male, living in the country, one evening when defecating in the woods was unfortunate enough to select a spot that was covered with poison ivy. When seen, three days later, he presented the most terrible spectacle of ivy poisoning the writer had ever seen. The cutaneous manifestation was severe, covering the whole scrotum, penis, groin, rectal and gluteal regions. Each testicle appeared to be the size of the fist, and the penis several times its natural size, puffy, and edematous. He was instructed to return to the spot of evacuation and to select a leaf from this particular plant, a part of which he was instructed to chew and to swallow the juice. This he did. There was a reduction of swelling, and the symptoms of itching and burning rapidly subsided, so that within three days he was able to resume his duties as butler. The reason for instructing him to return to the spot and chew the leaves of this particular plant was that there are several species of ivy and in attempting to treat the patient with the tincture from the fresh plant I might have given him a tincture of some ivy other than the one with which he had been poisoned.

The species of Rhus that are common throughout North America are Rhus glabra, Rhus venenata, Rhus toxicodendron, and Rhus aromatica; the last is the least poisonous. This method of treating ivy poisoning has long been known and employed by homeopathic physicians, who considered the cures resulting from the treatment as homeopathic cures, till the writer pointed out the fact that it was not a similar remedy, but the exact or the autotherapeutic remedy, for it treats the symptoms with the exact unmodified substance that caused them, and not a substance that causes a similar set of symptoms. Their failures, which they do not always record, may result from giving, as the remedy, a tincture of Rhus other than the one with which the patient was poisoned.

In the same way phosphorus poisoning may often be cured by giving the patient small doses of phosphorus, often repeated. The failures in this instance may have been from the same cause, but the percentage of cures has been such as cause it to be widely employed. The remedy given may not be of the exact chemical composition as the poison, often an impure product, while the substance given as the remedy may be, and usually is, the pure product.

Other autotherapeutic measures that may be cited are: Giving the unmodified snake and scorpion venom to cure the respective bites: and giving the virus of the mad dog to cure the effects of its bite. Other cures of a similar nature could be cited where the *exact unmodified substance that caused the symptoms is employed as the curative remedy.* This is the principle upon which autotherapy rests.

Our Readers' Monthly Prize Discussions

Twenty-Five Dollars Is Awarded for the Most Satisfactory Paper

All persons, whether subscribers or not, are invited to compete for the prize of $25 offered for the reply deemed best by the editors to the following questions:

CLXXV.—How do you treat furuneulosis? (Closed.)

CLXXVI.—How do you treat Colles's fracture of the radius? (Answers due not later than November 15th.)

CLXXVII.—How do you treat delirium tremens? (Answers due not later than December 15th.)

The award will be based solely on the value of the information contained in the answer. No importance will be attached to literary style. Answers should preferably contain not more than six hundred words, and should be written on one side of the paper only. All papers submitted become the property of the JOURNAL, and should bear the full name and address of the author for publication. The prize will not be awarded to the same person more than once within a year.

The prize of $25 for the best answer to Question CLXXIV has been awarded to Dr. Melville A. Hays, of New York City, whose paper appears below.

PRIZE QUESTION NO. CLXXIV.

THE TREATMENT OF IVY POISONING.

BY MELVILLE A. HAYS, M. D.,
New York.

The type of dermatitis venenata due to contact with Rhus radicans, or poison ivy, is caused by the active principle of the plant, toxicodendric acid, which is a volatile oil or oleoresin. Poison ivy grows in great profusion on rocks, trees, shrubs, stone walls, etc., in fields, woods, and parks; poisoning may occur at all seasons, but is most frequently met with in the summer months.

Sodium bicarbonate being an alkali, neutralizes acids; it also has the property, not usually mentioned in textbooks, of saponifying light oils and certain fats. Since the causative agent in ivy poisoning is both an acid and an oil or oleoresin, sodium bicarbonate is naturally the best remedial agent for the treatment of the condition. It is used as follows:

The affected parts should be well sponged with a cold saturated solution of sodium bicarbonate, and wrapped in gauze which has been thoroughly moistened with the same solution, the moist condition being maintained by adding fresh solution, and covering the entire dressing with oiled paper or oiled silk; on the face or other parts of the body, where it is difficult or impossible to retain dressings, the parts may be frequently sponged with the solution, or a thin paste made with cold water may be applied. Hair is turned a dirty brown color by strong solution of sodium bicarbonate, hence diluted Burow's solution (solution of aluminum acetate) or a one in 10,000 solution of mercury bichloride may be substituted for use about the forehead, the moustache, or the beard. In children where it is difficult to retain dressings while asleep, the sodium solution may be used at frequent intervals during the day and replaced at night by a five or ten per cent. watery solution, or ointment of ichthyol; the same method may be used with older persons when appearance is of little importance.

Prevention rather than cure is the aim of medicine. Ivy poisoning may be prevented by thorough washing of the exposed parts of the body with the saturated solution of sodium bicarbonate after every probable exposure.

During nearly five years' service on the new Catskill aqueduct (1909-1913), where poison ivy is always found in abundance, the writer used the foregoing method of treatment in hundreds of cases, both for prevention and cure, with splendid results.

Dr. J. D. Arnett, of Pavilion, N. Y., directs:

Prophylactic. Wash the exposed parts in a saturated solution of sodium bicarbonate or a solution of carbolic acid, one teaspoonful to a pint of water.

Acute stage. Do not cover the eruption with cotton or bandages, but leave exposed to the air, and apply a carbolic acid solution one in sixty every three hours, with cotton compress; apply until vesicles have a whitish appearance. The serum that collects may be washed away gently with sodium bicarbonate solution. Do not rub nor break the vesicles if possible. After the acute stage has subsided and the eruption becomes crusted, apply a zinc oxide ointment, to prevent cracking of the skin. Keep the parts covered for several days. If any constitutional disturbance manifests itself during the acute stage, a saline purge is indicated.

The skin should be kept clean by daily baths, using no soap, but with sodium bicarbonate added to the water.

Dr. H. J. Achard, of Chicago, writes:

It would be futile to enter into the many methods that have been suggested for the treatment of ivy poisoning, because, at most, they afford only temporary and transitory relief. The most successful methods of all those proposed consist in bathing the parts with alkaline solutions, in sponging with alcohol, and in applications of iodine. An interesting method is referred to by Doctor French in *Clinical Medicine* for September, which was proposed by a homeopathic[1] friend of his, and has been very successful for a number of years in a construction gang of railroad workmen, the foreman of which vouches for the efficacy of the treatment from his own experience. It consists in chewing some of the young leaves of poison ivy and swallowing the juice. Since doing so, they have all been free from rhus poison, while before, from eight to ten members of the gang were always laid up during the season.

Personally I have obtained gratifying results from bathing the affected parts in a solution of mag-

[1]Competent homeopaths deny that this is a real *Similia* treatment. See Duncan, page 901, this issue.

nesium sulphate, one heaping tablespoonful to the quart, and in keeping those parts of the body which were affected by the poison, covered with cloths soaked in the same solution. In all cases where this treatment was applied, the irritation diminished immediately and the dermatitis disappeared in the course of a few days. I have in mind a school girl, eighteen years old, whose face and arms were badly swollen and inflamed last summer from rhus poisoning, and who was relieved from her distress in the course of a few hours, although it took four or five days for the redness and swelling of the skin to disappear entirely. I have found it a good plan to open the bowels freely by means of saline laxatives, and to exclude from the diet all irritating substances, permitting only bland and easily digested articles of food.

Dr. J. Otis Carrington, of Malden, Mass., observes.

When a person has been exposed to the plant and is known to be susceptible, he should scrub his hands and face with hot soapsuds as soon as erythema first appears, followed by alcohol. Absorbent cotton or lint soaked in a saturated solution of sodium bicarbonate and applied continuously to the parts affected is very grateful during the day, while at night diachylon ointment (half strength) or zinc ointment is valuable.

Sometimes dermatitis venenata can be aborted in the early stages. The affected area is completely covered with flexible collodion. The following will also sometimes abort:

℞ Zinci oxidi, ... } .....āā 4 drams;
Magnesii carbonatis, }
Aristol, ... 8 drams;
Aquæ rosæ, ...q. s. ad. 120 drams.
M. et Sig. Apply locally three or four times a day.

Lead water and laudanum are valuable for allaying the pain, burning, and itching, but should not be used when the skin is broken. It should be combined as follows: Lead subacetate four parts, laudanum one part, water sixteen parts, to be varied according to severity of inflammation and pain.

Vesicles or bullæ should be incised under aseptic conditions, care being taken to prevent the contents from touching unaffected parts of the skin. After incision, paint the involved areas with fifty per cent. solution of ichthyol and, when dry, sprinkle with a light dusting powder and bandage lightly.

An aqueous solution of aluminum acetate two to five per cent. on gauze is good after incision. Also the following:

℞ Sodii hyposulphitis, ... 30 drams;
Glycerini, ... 15 drams;
Aquæ, ...ad. 240 drams.
M. et Sig. Apply locally three or four times a day.

Grindelia robusta one part and water ten parts also aid in causing subsidence of the eruption. Black wash (lotio nigra) is valuable where the case is not extensive and should be applied for half an hour at a time, two or three times a day. In extensive cases, the following is serviceable:

℞ Zinci oxidi, ... 16 parts;
Phenolis, ... 4 parts;
Aquæ calcis, ...q. s. ad. 500 parts.
M. et Sig. Apply locally on gauze three or four times a day. Poison—for external use only.

An aqueous solution of boric acid may be used intermittently during the day, applied on cheesecloth compresses.

After the eruption becomes dry and scaly, but itching persists, use calamine lotion; it acts splendidly:

℞ Pulveris calaminæ, . } .....āā 16 parts;
Pulveris zinci oxidi, }
Glycerini, ...āā 8 parts;
Sodii biboratis, ... 4 parts;
Acidi phenici, ... } .....q. s. ad. 240 parts.
Aquæ calcis, ... }
M. et Sig. Apply locally on gauze three or four times a day. Poison—for external use only.

At night use carbolic oil (phenol one part, olive oil nineteen parts).

Guard against using irritating lotions or soaps or anything that may cause a dermatitis, as the skin will be very susceptible to irritants. Should eczema ensue, apply calamine lotion. If constitutional disturbance is severe, treat on general medical principles.

Dr. S. Weingrad, Mountain Dale, New York, remarks:

Before considering the treatment of poison ivy, it is well to remember that its poisonous property lies in a nonvolatile oil (toxicodendrol) which is present in all parts of the plant, even in the wood after long drying.

It seems to be well proved, as many a patient tells me, that on their first day of arrival in the mountains, not having come in contact with any grass, they become affected with the poison. To account for this, some believe that the active principle may be an acid similar to crotonoleic acid, which is volatile, while others suppose the oil to be carried by the pollen.

When the plant is applied to the skin, after a few hours the patient experiences an intense itching and burning followed by swelling of the skin of the affected parts with a papular eruption which to the untrained eye may look like hives or one of the infectious eruptions.

I have used with success in a number of cases during the summer months the following treatment:

I order the patient to make a thick suds of plain laundry soap to be applied to the affected parts until it dries up. This usually takes about ten minutes, and is to be followed by a washing of the dried soap suds with a lysol solution, one dram of lysol to two quarts of cold water. When the itching is intense, I order some resinous ointment before bed time; this, by the way, is very seldom needed.

Dr. A. L. Taylor, of Fort Worth, Texas, states:

A victim is more susceptible in the spring than at any other season of the year. The attending physician should use all necessary precaution to prevent the spread of infection to other parts of the body, that is, if the case is seen early enough. In case of a small child, its hands should be confined or well wrapped up. An adult should be instructed not to scratch other parts of the body, for in this way infection is spread.

We find some cases in the chronic form that require symptomatic treatment, but I must say that

seldom, if ever, when treated according to my method will you find such cases.

For all practical purposes the following remedy has never failed me, neither have I seen it fail in the hands of others.

Take cream from freshly skimmed milk and copper sulphate. First powder your sulphate well, then to an ounce of cream add five grains of the powder. Mix and make a paste. Smear lightly over the irritated surface. Do this three times daily.

It seldom takes over three or four applications and the dermatitis disappears in from twenty-four to forty-eight hours.

Dr. Harry Koplin, of Springfield, Mass., with admirable conciseness, suggests:

Protect healthy area by rubbing in a little petrolatum. The affected area should be washed thoroughly with soap, water, and brush.

After that apply fluidextract of grindelia robusta one part to nine parts of water.

Abstracts and Reviews

A CLINICAL AND EXPERIMENTAL STUDY OF THE METASTATIC ARTHRITIDES.*

By the Late John B. Murphy, M. D.,
Chicago,
And Philip H. Kreuscher, M. D.,
Chicago.

(*Read by the Latter.*)

Dr. Philip H. Kreuscher began his address with a eulogy of the late Dr. John B. Murphy. In summing up his qualities, Doctor Kreuscher said that nothing was so typical of the life of the great surgeon as the quotation found after his death in his day book: "He went away nobly careless of himself, thinking only of the things he had endeavored to do."

In considering the subject of the present lecture, stress was to be laid on the following points:

1. Every case of acute joint infection was a surgical lesion and must be treated surgically.

2. These lesions, which had been thought to be infections in the joint cavities, were in reality infections about the joint.

3. There was a definite incubation period for every type of infection.

4. The joint fluid contained no bacteria in a large proportion of the cases.

5. Metastases to the joints occurred because of a definite, logical reason.

The etiological factors, symptomatology, diagnosis, and treatment of joint infections were considered in compiling this report. Tuberculosis of the joints was not included, nor the trophic joint involvements of syphilis.

Metastatic arthritis was an infection in or about the joints due to the invasion of pathogenic organisms which had been harbored and were capable of multiplying within the tissues of the host. The acute, subacute, and chronic varieties were distinguished and the monarticular, biarticular, and polyarticular types were named. The cases were classified etiologically into those due to a known pathogenic organism and those in which the origin could not be found. Pathologically, the acute or chronic serous acute, chronic suppurative, and the fibrinous or plastic types of arthritis were recognized.

Anatomy. In order to appreciate the problems in the management of these infections, it was necessary to keep in mind the synovial membrane with its layers, its pockets and diverticula, and the blood supply of the joints.

Etiology. In considering the causative agents, it was necessary to include the specific, exciting, etiological factors and the predisposing causes, as well as the atria through which the microorganisms gained entrance into the body.

It was found that the tonsils, the teeth, Neisserian infection, accessory nasal sinuses, infections of the respiratory, genitourinary, and gastrointestinal tracts had been the seat of the primary infection, the involvement being in the order named.

The streptococci, gonococci, pneumococci, and colon bacilli, singly or in mixed form with staphylococci, were responsible for most of the lesions. Nearly every case of chronic joint involvement was found to have had a number of lesions, with as many separate and distinct organisms. One patient who had an arthritis of fifteen years' standing was found to have infected tonsils, alveolar abscesses, accessory nasal sinus infections, and a severe pyelitis. Four distinct organisms were found.

Of the predisposing causes, trauma of the joints was to be mentioned, especially that of the spine which was so prevalent among those pursuing agricultural occupations. There were four such cases in Doctor Murphy's clinic at one time.

Incubation. There was a definite incubation period for nearly every type of joint infection. The failure to recognize this had caused the profession to overlook the connection between the primary infection and the resulting arthritis. From analysis it was found that Neisserian arthritis did not occur until from eighteen to twenty-two days after the primary urethral, vaginal, or ocular infection, or a secondary exacerbation. Joint lesions following infections from the upper air passages occurred between the tenth and fourteenth day after the primary manifestation of the trouble. Furuncles and carbuncles, usually due to mixed infections, caused metastases to the joints from the eighth to the fourteenth day. Infections of wounds of the extremities, for instance, those of staphylococcic or colon bacillus origin, showed manifestations about the tenth day. Streptococci, however, could cause a metastasis within forty-eight hours.

Metastasis did not usually take place, except in a pure streptococcic infection, unless a mixed infection occurred. In striking contrast with the streptococcic cases were the very late manifestations of the arthritic involvement of typhoid. These came from the fourth to the eighth week, or about the time that the typhoid ulcers were healing, or had healed.

Symptoms. The pain and swelling, constant

*Abstract of the Wesley M. Carpenter lecture, read at the New York Academy of Medicine, October 19, 1916.

symptoms in the acute cases, might be mild or apparently absent in the subacute or chronic cases. Chills and fever were rarely present when the trouble was of insidious onset. Luxation deformities and ankylosis were late manifestations of the disease.

Diagnosis. It was necessary to differentiate tuberculosis, chronic osteomyelitis near the joint, sarcoma involving the epiphysis of the bone, Charcot joint, and Schlatter's disease. After finding that the lesion was one of joint infection, it was advisable to find the atrium of infection and the causative organism in each individual case. Diagnosis of the type of infection could not be made from the joint fluid. In thirty-seven cases, only one showed a positive bacterial growth on the culture. Of course, these patients had not been aspirated, injected, or previously treated.

The infection was found to be periarticular, and only in rare instances did the bacteria pass directly into the joint cavity. Culturally and microscopically the fluid and tissues taken from three distinct cases of hypertrophic villous synovitis showed negative bacterial findings. On one occasion, however, pathogenic organisms were isolated from the synovial tissue of a case of chronic arthritis.

Treatment. Every case of joint infection was a surgical one and must be treated surgically. While it was not always possible to control infection, or prevent ankylosis, distortion could be controlled and the horrible, disfiguring deformities, resulting from these infections avoided. The plan of treatment was as follows:

1. Aspiration of the joint to relieve the tension of the infection products in the acute cases. Drainage tubes, when inserted into the joint, caused ankylosis in ninety-six per cent. of the cases.

2. A Buck's extension must be applied to relieve the intraarticular pressure on the bone ends. It must be applied on the first day in every case of acute arthritis.

3. A cofferdamming and infiltration of the lymph spaces must be produced by the injection of an antiseptic solution into the joint.

4. The focus of infection must be removed.

5. Deformities must be avoided by the application of extensions, Travois splints, plaster casts, and other appliances.

6. Autogenous vaccines were of value, if made and exhibited scientifically for the lesions for which they were intended.

Prevention. By way of prophylaxis, it was the duty of every physician to advise his patients that infected tonsils, abscessed teeth, and a chronic nasal discharge sometimes led to joint infections. Prophylactic management of even the most trivial disorders should be instituted.

A review of 859 cases gave the following statistics:

Age incidence.—Seventy-five per cent. of patients were from ten to forty years old. The period of greatest susceptibility was between thirty and forty years.

Sex incidence.—Sixty-one per cent. were females.

Season incidence.—Seventy-six per cent. had onset in late fall or winter.

Trauma incidence.—In ninety per cent. there was a history of definite trauma preceding the joint infections.

The proportion of the localization of the focus of infection was as follows:

	Per cent.		Per cent.
Tonsils	25	Appendix	2
Teeth	18	Gallbladder	2
Urethra	17	Furunculosis	6
Sinuses	17	Typhoid fever	6
Lungs and bronchi	5	Scarlet fever	6
Bladder	4	Tetanus	6
Kidney and pelvis	4	Dysentery	6

The proportion of causative pathogenic organisms was:

	Per cent.		Per cent.
Streptococci	31	Colon bacillus	4
Gonococci	14	Combination of two or more	38
Staphylococci	8		
Pneumococci	5		

Incidence of joint involvement was polyarticular in seventy-eight per cent. Type was chronic in sixty-six per cent.

Involvement of both extremities and spine occurred in seventy-three per cent. Seventy-four per cent. subsequently had chronic partial incapacity.

Experiments determined the intraarticular pressure resistance of human joints to be from thirty-five to fifty pounds to the square inch in the hip and sixty to 120 pounds in the knee.

After numerous experiments with formalin, it was found that a two per cent. solution in glycerin, mixed twenty-four hours before using, was the most suitable antiseptic for joint infections.

From a series of experiments it was concluded that the localization of a metastatic infection in a large percentage of the cases occurred outside the joint. The tissues immediately surrounding the joint were usually involved rather than the joint surface itself.

Clinically and experimentally, it was found that, except in the pure streptococcic infections, metastasis did not usually take place unless a mixed infection by an organism of another strain, or of a different variety, was superimposed upon, or concomitant with the first or primary infective organism. Metastases followed an acute cold, acute sinusitis, and acute alveolar abscesses in patients who had had a chronically diseased mouth and throat condition. In other words, a metastasis from a staphylococcic pyorrhea, or a staphylococcic alveolar abscess did not usually take place unless a foreign strain staphylococcic or a streptococcic infection superimposed itself upon the original infection in the form, for instance, of an acute root abscess or gumboil.

It had not yet been decided whether the rapidity of the metastasis depended upon the specific infectious organism, or upon the variety and virulence of the mixed infection.

Contemporary Comment

Holes in the Harrison Law.—In June, Justice Holmes of the United States Supreme Court handed down a decision in the Jin Fuey Moy case which interpreted the Harrison Narcotic Act as a revenue measure, controlling dealers and physicians, but in no way holding the mere possessor or user of narcotics liable to the law. This resulted in making it impossible for United States attorneys to continue prosecutions, as formerly under the act, against mere possessors of the drug. The

Texas statute is far superior and in many instances, observes the *Texas State Journal of Medicine* for October, 1916, county attorneys must take up the work of fighting the narcotic evil, in place of the United States attorneys, if results are to be accomplished.

Now comes Federal District Judge Bourquin, in Montana, with a decision, which, if it stands, will exempt the prescribing physician from one of the restrictions placed upon him by the official interpretation of the statute. He decided, in effect, that there is no restriction in the law against the prescribing of any quantity of a narcotic. He says:

> In said law is nothing prescribing quantities or forbidding orders or prescriptions for the drug in any quantity. Any attempt to find it therein by construction or implication does violence to that elementary principle, that when legislatures undertake to create offense it must be in language clear and definite, making it obvious to ordinary intelligence that by a certain conduct a crime and the offense denounced by the statute is committed. Hence such construction or implication is never permitted.

It has all along been evident that the law has been so soldered over by departmental rulings as to make a clear view of the statute impossible. The courts are slowly melting this away, until the act now seems so leaky that it will hold nothing unless Congress soon does some recasting.

A Judicial Blunder.—If newspaper reports are true, a Chicago judge has given a man convicted of an assault on a little girl the alternative of being sterilized by vasectomy and freedom, or twenty years in the penitentiary. Naturally, observes the *Chicago Medical Recorder,* for October 15, 1916, the man accepted vasectomy.

Evidently the judge thought vasectomy and castration the same in effect. He should have known that vasectomy in no way destroys the sex instinct or desire. The only good vasectomy does is to prevent a man from reproducing his kind. He will have the same desire to assault other little girls after vasectomy as before, and it is no fit punishment for his crime. It may well be questioned whether the judge will not be culpable in case the convicted man repeats the offense.

The Doctor on the Border is depicted true to life by W. H. Blodgett in a letter to the *Indianapolis Medical Journal.* He writes:

Four thousand Indiana soldiers taken from a healthy temperate climate to a climate filled with pestilence, from a land of peace and plenty to a land where poisonous reptiles and poisonous insects abound. They were dumped into a wilderness without water to drink or water to bathe in and there was no sanitary preparation. The rain beat down upon them, some of them slept in mud. The storms tossed them about, a blazing sun burned their skin, and the hot sands scorched their eyes. The war department sent out bulletins calling attention to the very small sick rate in the camp, but made no mention of the men who were responsible for that extremely small sick rate. No credit was given to the doctors on the border who certainly were entitled to a very large share of the credit. It is not much of a compliment to the doctor on the border if he has a large sick list and so he has to work the harder to keep his sick list down to the minimum; and sometimes he may send a man back to duty who should be in quarters. But during the three months I was there I never knew a doctor to mark a man for duty who should be in the hospital and I watched the hospital record and the work of the doctors closely because the folk back home were anxious about the health of their dear ones. One of the things the doctor on the border has to contend with and against which he has to be on a constant lookout is a staller. With a staller, or the hypochrondriac, the civil life doctor can use his own time and methods in dealing, but the army doctor must act at once. Sick calls on the border come just before the hour for drill and it is to keep off the drill ground that the staller is the most ingenious. A rookie was before the examining doctor.

"What's the trouble, my man," asked the doctor, looking at the soldier.

"Bad wound in my leg, sir. Something bit me, sir."

The keen eye of the doctor saw that the bad wound was a stab, and by examination he found that the staller had deliberately stabbed the calf of his leg with a bayonet in order to get into the hospital and escape drill. Instead of the hospital, the staller got into the guard house and did hard labor for thirty days on a bread and water diet. No doctor in civil life could have dealt with a staller in that way.

Another was suffering, apparently, the greatest agony. He declared that "appendicitis had got him bad," but the medical officer was wise to the situation. He placed the supposed sufferer on a cot and called in several other doctors, each of whom made a careful examination, with the utmost solemnity, and then they went just outside the tent, but within easy hearing distance of the supposed sick man:

"That's the worst case of desmachymatous I ever knew," said one of the doctors loud enough for the man within the tent to hear. "I think only an operation in gastrocomy will save him."

"I don't think we ought to go that far," spoke up another doctor. "We should at least save one of his legs."

"He cannot stand more than one amputation," said the first doctor. "Which leg shall we take off."

There was a rush from inside the tent and the staller was seen streaking it across to his quarters and later was in the drill squad.

A lad was before the medical officer for examination and was complaining of all kinds of pains and a variety of aches. The doctor looked him over.

"My boy," said the medical officer with a shake of the head, "I'm sorry to tell you you have a very bad case of nostalgia."

"Good Heavens, doc, if my mother knew that she would go wild. How in the world did I ever get it?"

"This climate breeds all sorts of things," said the doctor. "You go back to your quarters and I'll see you later."

In a short time the lad was given a detail of light work that kept him busy all day and kept his mind off his home and in a few hours his home sickness was gone.

Editorial Notes and Comments

NEW YORK MEDICAL JOURNAL
INCORPORATING THE
Philadelphia Medical Journal
and The Medical News
A Weekly Review of Medicine.

EDITORS
CHARLES E. DE M. SAJOUS, M.D., LL. D., Sc. D.

NEW YORK, SATURDAY, NOVEMBER 4, 1916.

A SUBSTITUTE FOR THE SPHYGMOMANOMETER.

We all meet with practitioners, mostly of the old school type, who are inclined to scoff at instruments of precision. We knew one such who never carried a stethoscope, while his colleague and bosom friend was never without one—would return to his office if by chance he started on his rounds without it. The former gentleman—the one without the stethoscope—always maintained that he could hear better with his unaided ear than his friend could with his instrument and, moreover, was fond of boasting that his ear he always had with him, while stethoscopes were easily mislaid.

The rank and file of the profession, however, have become so accustomed to various aids to diagnosis that their loss would be keenly felt. Next to the thermometer and the stethoscope perhaps the most valuable of these accessories is the sphygmomanometer. We all pride ourselves on the amount of information conveyed to us by the simple feeling of the pulse, but there are many pathological conditions associated with changes in the blood pressure where we feel the need of a more accurate estimate, and rely upon the sphygmomanometer.

Suppose, however, that one of these instruments is not available and we wish to determine whether or not the blood pressure is elevated; where we are undecided, for instance, between a diagnosis of senile dementia, which is essentially chronic, and of arteriosclerotic psychosis, which should end in recovery, the diagnosis may depend somewhat on the blood pressure and yet the patient may be too irritable to permit of any such procedure as the application of the sphygmomanometer. From a French physician, Doctor Molle, comes the announcement of a simple means of estimating blood pressure with fair accuracy without the aid of an instrument. The physician, standing on one side of the sitting patient, asks him to cross his legs. In subjects whose arterial tension is increased, the upper leg, viewed from the side, shows an oscillation synchronous with the arterial pulsation; this is due to partial obstruction at the level of the popliteal vessels. The oscillation, according to Molle, becomes apparent when the systolic pressure reaches 160 mm. or more; over 170 it is marked. The sign can be made more striking by covering the leg with a piece of paper. A little practice with this method and a comparison of its estimated results with the actual blood pressure will add one more trick to the repertoire of the "snap diagnostician."

WHEN CALOMEL IS CONTRAINDICATED.

Dr. A. Satre, in *Paris médical* for October 14, 1916, states that in fifteen years of practice he has never had a case of mercurial salivation from the exhibition of calomel. After giving details of three cases which fell into his hands from those of colleagues, he summarizes his precautions. In the first place, he says, the prescriber must never forget the chemical composition of calomel, i. e., that it is a protochloride of mercury. Then calomel must never be exhibited where there is renal disease; this means that it is best not to give it to patients over fifty years of age, a time when the kidneys are justifiably under suspicion. Before prescribing calomel, there should be a searching examination of the mouth and teeth, and it is best to substitute some other cathartic if there is the slightest sign of gingivitis, of carious stumps, or of a heavy layer of tartar. In addition, Satre always precedes the exhibition of calomel by prescribing preventive mouth washes and gargles, based usually on potassium permanganate or thymol, as well as an alkaline tooth powder. His favorite powder is the following:

Potassium chlorate, ... 20 grams;
Sodium borate, ...
Calcined magnesium (heavy), ... āā 40 grams;
Menthol, ... 1 gram.

By taking all the foregoing precautions, Satre is glad to say that he has been able to use a most excellent remedy in many cases where the condition of the teeth left much to be desired.

THE ANTIQUITY OF MAN.

The date of the origin of the human species, by each new discovery of missing chapters in its history, is shifted to a more and more remote time. The Neanderthal skull, which, by its prominent supraorbital ridges, its length, and flattening from above downward, seemed to link man closely if loosely to the higher apes, still had a brain capacity quite equal to that of the average modern man and, on this account, pointed to a still more remote beginning of the human being. The brain of Neanderthal man was not only large but elaborate and, as shown by the remains of his culture, he possessed fire and made flint implements. Though ancient he was anything but an ape. The Heidelberg skull, which resembled the Neanderthal remains but was still more markedly simian in general features, had also a capacious brain case and is believed to have belonged to a creature with comparatively high mental development. The Neanderthal man is placed some 300,000 years back, while the Heidelberg skull is presumed to date to a doubly remote time.

The prehistoric remains found by Doctor Dubois in Java, the bones of Pithecanthropus, as he has been called, were of decidedly earlier geological date, as indicated both by their surroundings and by their own features; the brain case was small and the cranial traits were otherwise more apelike than those of any other known remains. "All the structural characters of Pithecanthropus, so far as we know them, are exactly of the kind we expect to find in the early ancestral type of man." The unearthing of the Java man pushed the date for the origin of the human type backward another period of a few hundred thousand years, or into the Miocene epoch of geological time.

The chain linking modern man directly with an early type similar to the gorilla or chimpanzee seemed to be growing strong until, in 1912, the bones of an ancient man of another type were discovered in England in the Piltdown cave. This, according to Dr. Arthur Keith, who is as great an authority as can be found, is the "oldest specimen of true humanity yet discovered." The brain of this being was, in size at least, up to the modern standard, but otherwise the bones are "the most simian recorded."

According to Doctor Keith's reasoning, we can no longer consider all these ancient remains as linking us in one line with our apelike ancestor, but, in his restoration of the family tree, the Java man, the Neanderthal and Heidelberg man, the Piltdown man, and modern man have all sprung from the same original stem, which dates back some two million years to the Oligocene epoch, when, in turn, it diverged from a parent stem from which the great orthograde primates, and earlier, the small primates and monkeys developed.

Although these early remains are few, and their restoration is not without difficulty, our notions of the age of man and the steps of his evolution have been much modified by the information they disclose. It is certain that there exists today on the earth, in the person of the Australian native, a type of human being as low in brain case capacity, and in mental development, as any of the types revealed by the prehistoric remains, for, while even the Java skull had room for about 1,500 c. c. of contents, the skull of the aboriginal Australian has a capacity as low as 930 c. c. As Doctor Keith puts it, there are living remains of man in Australia older than any fossil forms of modern man in Europe. It is not impossible that these living men are direct representatives of the type from which even the fossil types sprang, and which has persisted, though the latter have disappeared from the face of the earth. They may also represent the stock from which the living races, African, Mongolian, and European, have developed.

YEAST AS FOOD.

Abnormal conditions of food supply caused by the European war are bringing about one scientific result of no small interest. This result follows the effort to utilize unusual food sources and especially to find substitutes for certain important food elements. Thus considerable work has been expended on the utilization of food elements in straw and other available, but ordinarily unassimilable substances. The scarcity of meat in Germany has caused a serious search for substitute nutritional substances, and among the articles considered has been yeast, in which it seemed possible to find available nitrogen as well as active vitamine principles.

A recent paper by Funk, Lyle, and McCaskey in the *Journal of Biological Chemistry* for October, 1916, takes up this last problem. These authors find rather a low biological value for yeast as a source of protein. This is partly due to the large percentage of ingested yeast which passes with the feces, to the difficulty of preparing it in palatable form, and to the fact that yeast definitely raises the blood content of uric acid.

The earlier findings of Abderhalden, Foder, and

Rose were confirmed, that a positive nitrogen balance was harder to obtain with a vitamine free diet of white rice and white bread, than with potatoes and whole grain bread. The experiments described were too short to decide whether the entire fault lay with a lack of vitamine. The authors suggest the importance of investigating yeast as a supplementary nutritional agent in communities suffering from dietetic deficiencies.

THE TRANSFUSION OF BLOOD.

Transfusion of blood is an operation of great antiquity, and a procedure which has always appealed to the imagination. Shelton Horsley, in his work on the surgery of the bloodvessels published a short time ago, mentions that the idea of rejuvenation by transfusion is to be met with in Ovid's *Metamorphosis,* while Pope Innocent VIII, when in a state of coma, was transfused three times, without benefit to himself, and unhappily at the cost of the lives of three donors. The method has now and then been abandoned, mainly because of the difficulties in the way of its successful completion. Of recent years, however, stimulated largely by the work of Crile and Carrel, and chiefly, perhaps, as the result of the simplification of technic, the method has come into vogue again and is frequently employed. Indeed, a great deal of ingenuity has been exercised in the invention of cannulas or tubes to facilitate the operation, some of which appear to fulfill in a satisfactory manner the object for which they were designed.

Horsley advocates the method of direct suturing of the vein of the recipient to the artery of the donor. End to end anastomosis of artery to vein, however, is not possible when rapidity of operation is incumbent, and this is frequently the case. Moreover, the method predicates for its success, the possession of considerable skill on the part of the operator and assistants, and therefore is not well adapted to the exigencies of war. The European war has brought direct transfusion of blood into prominence, as manifestly there are numerous occasions when its revitalizing effects are urgently needed. According to some Canadian surgeons who have had experience in war surgery on the European battlefields, surgeons from the British Isles have been chary of employing the method, and it has been left to their brethren from the Dominion to test the value of the remedy on soldiers suffering from loss of blood and shock.

In the *British Medical Journal* for July 8, 1916, L. Bruce Robertson, of Toronto, gives his views as to the therapeutic merits of transfusion of whole blood regarded from the standpoint of the wounded soldier. Robertson first points out that the broad indications for blood transfusion are based on the fact that transfused blood is the best substitute for blood lost in acute hemorrhage and is thus eminently suited for use in war. In fact, it may be granted that its employment is indicated in certain conditions which are apt to be encountered in war, provided that the supply of healthy donors is at hand, and that the technic of the procedure is not only simple, but supplies the blood to the recipient in a rapid and satisfactory way. That is to say that the donors must be examined carefully, so that certainty exists that no disease can be transmitted—naturally syphilis must be especially guarded against—and that whole unmodified blood without clotting is transfused.

Robertson states that there is little or no difficulty in picking out a robust and healthy donor, who can withstand the loss of from 600 to 1,000 c. c. of blood without more than temporary disturbance, from among soldiers suffering from sprains, minor fractures, etc., but who are otherwise in good physical condition. No ill effects should be felt by a donor if at the end of a transfusion, a quantity of saline equal to the amount of blood withdrawn from the circulation is infused and he rests for the space of twenty-four hours. The good results are most apparent in cases of primary hemorrhage. In secondary hemorrhage, where the factor of sepsis has to be combated, the additional blood often carries a patient over a critical period, and aids the vital forces to withstand further surgical procedures necessitated by the infective process, or increases his resistance to such an extent that by his natural resources he is able to overcome the infection.

Primrose and Ryerson, in the *British Medical Journal,* for September 16, 1916, emphatically corroborate the statements of Robertson.

AN ENGLISH VIEW OF TWILIGHT SLEEP

In the *British Medical Journal* for October 14th. Dr. F. W. N. Haultain and Mr. Brian H. Swift discuss the morphine-hyoscine method of painless childbirth and give their conclusions as follows:

It is a safe and efficient means of managing labor painlessly in the majority of cases. It requires, however, the constant attendance of a competent attendant. This role can be efficiently undertaken by a trustworthy nurse under supervision, which makes its adoption in better class private practice possible to the medical practitioner. It is of special value in primiparæ, in whom as a rule the first and second stages of labor are long and painful. It is also of great value in a prolonged second stage, due to a large head or slightly contracted pelvis, as it allows of head moulding without unduly exhausting the patient.

So far as amnesia is concerned, it is of little use to begin the treatment during the second stage. The

strength of the uterine contractions is not diminished, hence its advantage over chloroform. There are no contraindications to its use beyond extreme restlessness, which is exceptional and is probably due to an idosyncrasy. The absence of exhaustion is one of its greatest advantages. Thirty-seven of forty patients arose from bed on the third day after labor.

It is to be regretted that such a great deal of publicity has been given to the subject, and that prominent specialists have allowed themselves to be exploited through the lay press, as the lay community suffers from the want of knowledge and sense of proportion, which allows of an estimate of its value under various conditions, and is, therefore, apt to attempt to force the hand of the careful practitioner.

A NEW OFFICIAL QUARTERLY.

The *Bulletin of the Department of Public Charities* makes its bow with the issue for October, 1916, promising to appear quarterly henceforward. The editor in chief, Orrin S. Wightman, B. A., M. D., presents 114 pages of excellent matter, drawn from the wealth of material at the disposal of the Department of Public Charities, with its 9,000 beds filled with patients of every kind. The contributors are all members of the various staffs of the hospitals under departmental control. The quarterly is solid reading matter and carries no advertising. The subscription price is two dollars a year. We extend a hearty welcome to the newcomer and shall be glad to see it prosper.

News Items

Change of Address.—Dr. George Hohmann, to Laurette Court, 2480 Grand Concourse, New York.

Aftertreatment of Poliomyelitis.—The November 14th meeting of the Philadelphia Pediatric Society will be devoted to a discussion of the aftercare of poliomyelitis patients.

Lutheran Hospital Dedicated.—The new home of the Lutheran Hospital, Convent Avenue and 144th Street, New York, was dedicated on Sunday, October 29th, and was opened to the public on the following day.

New Hospital Opened in Paterson, N. J.—The new $250,000 Nathan and Miriam Barnett Hospital was opened in Patterson, N. J., on Tuesday, October 24th, with suitable ceremonies. Among the speakers was Dr. Abraham Jacobi, of New York.

Fordham Medical Alumni Organize.—Medical alumni of Fordham University have organized an association, with the following officers, to serve for the first year: Dr. James McSweeney, president; Dr. John J. Sheridan, vice-president; Dr. Francis McGovern, secretary and treasurer.

Mount Sinai Hospital Clinical Society, Philadelphia.—The following officers were elected at the annual meeting of this society, held on Tuesday, October 17th: Dr. Simon Wendkos, president; Dr. Abraham I. Rubenstone, vice-president; Dr. Arthur M. Dannenberg, secretary and treasurer.

Connecticut Public Health Association.—This association, which was organized at a meeting held in Hartford on Saturday, October 21st, aims to ascertain the needs of the State in health matters and to coordinate the forces now working for public health interests. Dr. Stephen J. Maher, of New Haven, presided at the meeting.

Antitoxin for the Allies.—Health Commissioner Haven Emerson, of the Department of Health of the City of New York, reports that since the beginning of the European War the department has sold $205,000 worth of antitoxin, two thirds of which has been purchased by the Allies.

Physicians for the Central Powers.—Philadelphians of German and Austrian descent are making arrangements to send an expedition of six physicians to the armies of the Central Powers for six months. The expenses of the trip will be about $16,000, of which $10,000 has already been subscribed.

A Public Clinic in Genitourinary Diseases will be held every Thursday evening at 8:30 o'clock, by Dr. Abr. L. Wolbarst, at the West Side German Dispensary and Hospital, 328 West Forty-second Street, New York. The clinics began on November 1st and will end in April. Physicians and medical students are cordially invited.

Compulsory Health Insurance.—A public meeting to consider this subject will be held at the New York Academy of Medicine, under the auspices of the Committee on Medical Economics of the Medical Society of the State of New York, on Thursday evening, November 23d. The speakers will include men of national reputation and experts on health insurance.

Columbia University Dental School.—One contribution of $100,000 and another of $25,000 have been received toward the $1,000,000 foundation and maintenance fund for the Dental School of Columbia University. The giver of the larger amount stipulates that the money be spent to equip a room to be known as the William Jarvie Infirmary, in memory of his brother, Dr. William Jarvie.

Birth Control.—At a meeting of the Medical Society of the County of New York, held on Monday, October 23d, a committee was appointed to consider the advisability of changing section 1142 of the Penal Code, making it lawful for a qualified physician to give advice on birth control, and present a report at the December meeting of the society. Dr. Abraham Jacobi was made chairman of the committee.

Typhus Fever in Texas.—According to reports received in Washington, D. C., by the United States Public Health Service, during the two weeks ending October 16th six cases of typhus fever were reported at El Paso, Texas, making a total of 17 cases since July 1st. At Laredo, Texas, one case was reported on October 21st and another on October 23d, making a total of three cases since October 16th.

Clinical Lectures on Skin Diseases.—Dr. L. Duncan Bulkley began his eighteenth series of clinical lectures on diseases of the skin in the Out Patient Hall of the New York Skin and Cancer Hospital on Wednesday afternoon, November 1st, at 4:15 o'clock. These lectures are given every Wednesday afternoon at the same place and are free to the medical profession on the presentation of professional cards.

Personal.—Dr. William Sharpe, professor of neurological surgery in the New York Polyclinic Medical School, delivered an address on Recent Advances in Brain Surgery, illustrated by moving pictures, before the College of Physicians of Pittsburgh, Pa., at a dinner at the University Club, October 27, 1916.

Dr. Leon Brinkmann succeeds Dr. Melvin M. Franklin as visiting surgeon to the Jewish Hospital, Philadelphia.

Dr. Victor C. Pedersen will be at St. Mark's Hospital, 177 Second Avenue, corner Eleventh Street, Monday, Wednesday, and Friday mornings, 11 a. m. to 1 p. m., Tuesday evenings, 8 to 9 p. m., to examine urological cases in men, women, and children for operation and treatment in the hospital.

Dr. K. C. Haas has resigned as State Commissioner of Health of Kansas.

Dr. Bernard Glueck, who has been in charge of the psychopathic clinic recently established in Sing Sing Prison, has been appointed physician to the institution, succeeding Dr. Amos O. Squire, who has resigned

Meetings of Medical Societies to Be Held in Philadelphia during the Coming Week.—Monday, November 6th, Academy of Surgery, Clinical Association; Tuesday, November 7th, Wills Hospital Ophthalmic Society, Laryngological Society, Medical Examiners' Association; Wednesday, November 8th, County Medical Society; Thursday, November 9th, Polyclinic Ophthalmic Society, Pathological Society; Friday, November 10th, Psychiatric Society, Northern Medical Association.

Street Accident Fatalities in New York.—Police records show that the number of known deaths due to accidents during the month of October was 59, compared with 79 for the month of September, which was increased to 87 by a subsequent mortality in October. Last year the record for October was 61 at the end of the month, and 77 when the later mortality became known. The automobile was the chief cause of death, 20 fatalities being charged to its account, and there were 12 deaths from motor trucks.

Medico-Chirurgical Professors Added to Faculty of University of Pennsylvania.—The following former members of the faculty of the Medico-Chirurgical College of Philadelphia have been elected members of the faculty of undergraduate medicine of the University of Pennsylvania: Dr. Joseph McFarland, professor of pathology; Dr. John C. Heisler, professor of anatomy; George H. Meeker, Sc.D., professor of chemistry; Dr. Horatio C. Wood, Jr., professor of pharmacology and therapeutics; Dr. Seneca Egbert, professor of hygiene.

The Fundamental Principles of Good Lighting.—A lecture on this subject will be given at the Franklin Institute, Philadelphia, on Wednesday, November 8th, by P. G. Nutting, Ph. D., director of the research laboratory of Westinghouse Electric and Manufacturing Company, Pittsburgh. The question of visual sensibility, efficiency, and tolerance will be reviewed, and principles deduced governing visually efficient lighting. Ideal lighting will be described and applications to practical lighting will be outlined. The lecture will be illustrated. All physicians who are interested are invited to attend.

Development of Red Cross Teaching Centres.—The demand for the courses of instruction conducted under the direction of the National Committee on Red Cross Nursing Service has developed so rapidly that some of the Red Cross chapters in the larger cities have organized teaching centres. Directors of instruction or instructors for full or part time, as the amount of teaching would indicate, are employed to direct the teaching. The centralization of instruction under carefully selected directors or instructors, who must be enrolled Red Cross nurses, and approved by the bureau of nursing service at Washington, has been found to result in greater economy and more uniform teaching.

New Inspectors of New York's Charities.—Dr. John A. Kingsbury, commissioner of charities of New York, announces the appointment of twenty-one new inspectors of the city's charities. Commissioner Kingsbury believed that the inspectors were made necessary by the refusal of the State department to certify that the charitable institutions which draw money from the city were complying with all the requirements. Upon the ground that institutions which received city money should be inspected the board of estimate has established the new bureau of inspection. Quarterly inspections will be made of 305 institutions and semi-annual inspections of 22 agencies for boarding out dependents.

American Medical Editors' Association.—Dr. George Morris Piersol, of Philadelphia, editor of the *American Journal of the Medical Sciences*, was elected president of the association, at the forty-seventh annual meeting held in New York last week. Dr. George W. Kosmak, of New York, and Dr. Robert M. Green, of Boston, were elected vice-presidents, and Dr. Joseph MacDonald, Jr., of New York, was reelected secretary and treasurer. Dr. James P. Warbasse, of New York, acted as toastmaster at the annual banquet of the association, held on Thursday evening, October 26th, and among the speakers were Dr. Abraham Jacobi, Dr. H. Edwin Lewis, Dr. Henry O. Marcy, Dr. Ira S. Wile, and Mr. Paul U. Kellogg, editor of the *Survey*.

The Clinical Congress of Surgeons of North America.—At the seventh annual meeting of this congress, held in Philadelphia during the week of October 23d, the following officers were elected: Dr. John G. Clark, of Philadelphia, president-elect; Dr. George Henderson Lee, of Galveston, Texas, first vice-president; Dr. Edgar W. Allin, of Edmonton, Alberta, Canada, second vice-president; Dr. Franklin H. Martin, of Chicago, secretary-general (reelected); Dr. Allen B. Kanavel, of Chicago, treasurer (reelected); Mr. A. D. Ballou, of Chicago, general manager (reelected). Next year's meeting will be held in New York.

Harvard Appointments.—Fifty-seven appointments were confirmed at the last meeting of the corporation of Harvard University, among them being the following in the medical school: Dr. Edward H. Nichols and Dr. Charles A. Porter, clinical professors of surgery; Dr. Robert E. de Courcy Ward, professor of climatology; Dr. Arthur B. Lamb, professor of chemistry and director of the chemical laboratory; Dr. Roger I. Lee, professor of hygiene; Dr. Donald M. Glover, assistant in histology; Dr. Joseph H. McGuire, assistant in histology; Dr. MacIver Woody, assistant in pathology; Dr. Harry S. Bernstein, assistant in pathology; Dr. Francis L. Burnett, assistant in pathology; Dr. George Clymer, alumni assistant in neurology; Dr. LeRoy U. Gardner, instructor in pathology.

American Surgeons to Tour South America.—At the meeting of the Clinical Congress of Surgeons of North America, held last week in Philadelphia, announcement was made that the United States Government had requested the congress to select a number of prominent American surgeons to make a tour of Central and South America for the purpose of bringing the surgeons of the United States into closer professional relation with the surgeons of Latin America. The more prominent surgeons of South America will be invited to join the American College of Surgeons. Dr. Charles H. Mayo, of Rochester, Minn., Dr. Franklin H. Martin, of Chicago, Dr. Albert J. Ochsner, of Chicago, Dr. George W. Crile, of Cleveland, Dr. Edward Martin, of Philadelphia, and Dr. Frank F. Simpson, of Pittsburgh, were named by the congress for the Latin American expedition.

Medical Association of Central New York.—The forty-eighth annual meeting of this association was held in Buffalo on Thursday, October 19th, under the presidency of Dr. A. L. Benedict. At a luncheon given to the members by Dr. Lucien C. Howe, Colonel Jefferson R. Kean, of Washington, D. C., director general of military relief of the American Red Cross Society, spoke on medical and surgical preparedness for war and explained the details of the reorganization of the American Red Cross Society, whereby it became a part of the regular medical service of the military and naval forces of the United States. The following officers were elected: Dr. Ledra Heazlit, of Auburn, president; Dr. J. J. Buettner, of Syracuse, first vice-president; Dr. Charles Hennington, of Rochester, second vice-president; Dr. J. R. Burns, of Syracuse, secretary; Dr. T. F. Laurie, of Auburn, treasurer. Next year's meeting will be held in Auburn.

American College of Surgeons.—At the annual meeting of the college, held in Philadelphia during the week of October 23d, coincidentally with the Clinical Congress of Surgeons of North America, the following officers were elected: President, Dr. George W. Crile, of Cleveland; first vice-president, Dr. Robert R. G. Le Conte, of Philadelphia; second vice-president, Dr. Rudolph Matas, of New Orleans; secretary (reelected), Dr. Franklin H. Martin, of Chicago; treasurer, Dr. A. J. Ochsner, of Chicago. Chicago was settled upon as the permanent headquarters of the college. Announcement was made at the meeting that the American College of Surgeons had decided to form an international committee on standards, with representatives from each State in the Union and the Provinces of Canada, which will take the necessary steps for the enactment of laws to protect the public against untrained surgeons, and by legislative enactment and other means prevent dishonest practices, and finally to provide means for the supplementary and graduate training of surgeons.

Modern Treatment and Preventive Medicine

A Compendium of Therapeutics and Prophylaxis, Original and Adapted

THE THERAPEUTICS OF A PHARMACOLOGIST.

By A. D. Bush, M. D.,
Professor of Pharmacology and Therapeutics, University of Southern California.

Forty-third Communication.

STOMATITIS.

Of the several forms of stomatitis with which human flesh is afflicted discussion will be confined to the most frequent type—aphthous stomatitis, known generally among the laity as "canker." Small in latitude but mighty in its potentiality for discomfort, aphthous stomatitis is a disturbance of the alimentary tract deserving of careful investigation; yet very little is known concerning its etiology, and even less as to the means of suppressing it. Some pathologists think the ulcerative lesion is due to spasmodic constriction of the arteriole, reflex in origin, leading to necrosis of the area of supply; others ascribe the affection to bacterial invasion; some think it an unexplained manifestation of gastric disturbance; while still others believe the trouble to be due to local injury. With such variations as to the etiology there have inevitably been many suggestions as to treatment —none of which seems to possess any particular efficiency. Under the circumstances the pharmacological discussion must become preponderatingly speculative; but a few suggestions may not be amiss.

The appearance of the primary vesicle is almost invariably preceded by localized passive congestion of the adjoining tissue of gum and mucosa, particularly noticeable with those wearing artificial plates. This congestion, and the sense of pressure accompanying it, is a fairly sure herald that in the immediate vicinity a canker spot will soon develop. With the local symptoms there will also appear a mild salivation, some anorexia, a sense of gastric heaviness, and irritability; all pointing to a systemic disturbance. At this time, a light calomel purge, followed by a strictly limited diet, seems to prove abortive in a small percentage of cases, thereby indicating a probable gastrointestinal disturbance; but more commonly the local symptoms become acute, with the appearance of an exquisitely painful ulcerating patch.

Aphthous stomatitis seems to be a self limited disease, so far as each individual ulcer is concerned. In the discrete form the affection seems to run a course of nine days' duration, counting from the first feeling of pressure in the gums to the final healing of the ulcer, about equally divided between progressive aggravation, height of discomfort, and gradual decline; and medicines seem to be of little avail. If the difficulty is contriction necrosis, cleanliness is the local treatment, with bowel depletion as accessory; if bacterial invasion is the causative factor, local disinfection would be in order, but personal experience with chemical and electrical caustics, excision, and powerful germicides, seems to indicate utter uselessness of this mode of attack. The only local treatment seems to be palliative of the discomfort, and consists of the application, especially before meals, of a five per cent. solution of cocaine, the neighboring mucosa having been dried and walled off with cotton pledgets. This gives temporary relief in time of greatest need; the balance of time the distress is not usually unbearable. Internal treatment to correct gastrointestinal disturbances or other dyscrasia is helpful in averting a succession of attacks.

Potassium chlorate has been highly lauded by some writers, but it probably has no curative influence whatever; indeed, its chemical nature indicates no possibility of value in this trouble, unless the potassium base has some selective influence, in which case a less poisonous salt of potassium would be preferable. But whatever may be its value, it ought not to be given except in small doses, and not at all to children. Seek out the underlying cause.

Bacterial Vaccines in Pulmonary Tuberculosis. —S. G. Bonney (*Journal A. M. A.*, October 21, 1916) gives his observations of the effects of vaccine therapy in pulmonary tuberculosis as follows: That vaccine therapy should certainly not be used as a routine measure although it seems to have some place as a tentative measure in a certain class of cases. In all, the number of cases for which it is suitable is relatively small, its results are uncertain and the proportion of cases improved by it is very disappointing. In a few, however, the improvement produced is striking, but, on the other hand, vaccines frequently are very injurious. One of the most important factors in the use of vaccines in tuberculosis is the careful adjustment of the doses. Incidentally, the same statements may be made in general with regard to the use of tuberculin and in the case of both agents the profession should adopt an extremely conservative attitude. These impressions are supported by the citation of a few cases which have come under the author's observation and it is pointed out that there is no valid excuse for giving vaccines to patients who are doing well and that the results offer little encouragement for their use in cases which are declining rapidly. Finally, emphasis is laid upon the fact that the better cooperation of the patient in the general treatment and the encouragement given him by the belief that something is being done for him when vaccine is used are often chiefly responsible for the beneficial results. The greatest difficulties are encountered in the determination of the secondary organisms which are to blame for the nontuberculous portion of the disease and we can never be absolutely certain that the vaccine used is the right one. If a polyvalent mixed vaccine is used to overcome this difficulty one or more of the contained organisms may do great harm

Sublingual Medication.—W. Paulson (*Practitioner,* October, 1916) recommends the sublingual space as the most reliable place in the body for the rapid absorption of concentrated remedies directly into the circulation. This space has a considerable area, a thin membrane, which always is clean, never furred, and never shielded by mucus. A morphine and atropine disc powdered with the point of a penknife and dropped just behind the teeth, or an apomorphine disc similarly powdered will be absorbed in a few seconds, and the full effects of the dose may be depended upon to appear almost immediately. Compared with hypodermic injection he holds that the sublingual method is quicker, easier, safer, cleaner, and far more reliable. Three emergency cases are quoted showing the prompt effects of apomorphine when administered in this way.

Dysentery.—R. Tanner Hewlett (*Practitioner,* October, 1916) gives the following summary of the recommendations of the advisory committee for the prevention of epidemic diseases in the Mediterranean expeditionary force on the treatment of diarrhœa and dysentery, given in the *Journal of the Royal Army Medical Corps:*

a. Dietetic. In every instance the diet should be liquid. For the first twenty-four hours milk should be avoided and barley, rice, oatmeal, or albumin water, or chicken broth given. Afterward milk may be given, preferably diluted with water or barley water, and a little sodium citrate added, three or four grains to the pint. If milk cannot be tolerated, Benger's food, Brand's essence, bovril, and light soups may be substituted. No solid food should be given until the active processes in the bowel subside, when arrowroot, custards, etc., should be added with due caution.

b. Medicinal. 1: Diarrhea. A patient seen at the beginning should at once be given an ounce of castor oil; if colic is present, ten minims of tincture of opium should be added to the oil. This with rest, warmth, and a suitable dietary will often check the condition. It may frequently be followed by one dram doses of castor oil in emulsion, every four or six hours for twenty-four hours. At the same time, to be on the safe side, emetine should be given from the onset—two thirds of a grain once or twice a day. In severe cases which show every sign of passing into true dysentery, larger doses of emetine should be given—two or even three grains in the day, in half grain doses, every four or six hours. If the castor oil fails after a fair trial salines should be given. The following is a useful prescription:

℞ Sodii sulphatis, ...gr. lx;
Acidi sulphurici aromatici, ...ℳxv;
Tincturæ zingiberis, ...ℳvii-viii;
Aquæ menthæ piperitæ, ...ad ℥i.

This may be given every two, three, or four hours, according to the severity of the symptoms, and should be continued until the stools become watery.

2. Amebic dysentery. A dose of one grain of emetine hypodermically, given once, or at most twice a day, is usually ample to kill the amebas, but has no action on the ulcerative colitis, local treatment of which is generally indicated. For this purpose the foregoing saline mixture may be given every four hours, with a saline enema douche night and morning. Later, when blood has disappeared but mucus still persists, daily enemata of 150 grains of tannin and fifteen of quinine in a pint of warm water, may be substituted. If painful half strength may be employed. Tannin alone may be used, from a half to one per cent.; and calcium permanganate, six grains or more to the pint, is an alternative solution. A sedative enema of bismuth ℥ii, tincture of opium ℳxxx, and thin starch ℥ii, is sometimes useful. Warm linseed tea also forms a soothing injection. A suppository of cocaine and morphine will frequently facilitate the administration of enemata, and may benefit spasm and tenesmus as well. In severe amebic dysentery emetine should be given intravenously, as much as one and a half grain in ten c. c. of saline daily, in lessened doses as the case improves. If emetine is going to do good its beneficial action is quickly apparent. Failing emetine, the old ipecacuanha treatment must be tried. During convalescence bismuth salicylate should be employed if diarrhea persists. In all severe cases the tendency to heart failure must be borne in mind. When the condition becomes chronic local treatment is most useful, large enemata of copper sulphate, one to 1,000, or silver nitrate, with starch and opium.

3. Bacillary dysentery. Antidysentery serum should be given, if available. If salines are employed the sodium sulphate mixture mentioned above will be found to act well. In very bad cases, drained by incessant evacuations, intravenous injections of saline will often save life, but they must be used in good time. Chronic cases receive local treatment, similar to that for chronic amebic dysentery. In cases of doubtful etiology a combined therapy of emetine and polyvalent serum should be employed. In all forms colic is benefited by turpentine stupes to the abdomen, and hemorrhage may be controlled by morphine and adrenaline hypodermically, calcium chloride or lactate by mouth, or oil of turpentine in capsules.

4. Flagellate dysentery. The only parasite causing diarrhea or dysentery that can be satisfactorily treated is Trichomonas hominis. In the early stage an enema of boiled water should be given, followed by one of iodine, one to 1,000, given very slowly every evening for three consecutive days. If the parasites persist a tablespoonful of the following mixture should be given every two hours for three days:

℞ Infusi cinchonæ (1 in 50, not acid), ...℥iiss;
Extracti cinchonæ, ...℥iij;
Tincturæ cinnamomi, ...℥v;
Syrupi opii (0.5 ext. in 1,000), ...℥iij;
Tincturæ camphoræ compositæ, ...℥j;
Olei terebinthini, ...ℳxlviii.

with

Gummi acaciæ, ...℥ss;
Aquæ floris aurantii, ...℥ss;
Aquæ distillatæ, ...℥v;
Syrupi, ...℥ij.

In addition, the following enemata are indicated night and morning:

(a) Three and one half pints of decoction of eucalyptus.
(b) Two ounces of boiled water, yolk of an egg.
Ten minims of laudanum.
Fifteen minims of essence of turpentine.

The committee insist on the need for absolute rest and warmth to the abdomen in all cases of dysentery.

Nails and Screws Through Joint Surfaces.—Arthur T. Mann (*Journal A. M. A.*, October 14, 1916) has found, as the result of animal experiments and two human experiences in which nails or screws were used through joint surfaces in fractures or autografts, that both nails and screws were tolerated with astonishingly little reaction. The surface over them was covered with connective tissue and hyaline cartilage, and the joint was left free and mobile. Autografts also united perfectly and seemed to live, but were ultimately replaced by the ingrowth of new bone and the absorption of that original to the graft. Condyles also united like free autografts. Projecting bodies were covered by new tissue and thus removed from the joint surface. These observations showed the possibility of satisfactory employment of these mechanical means in the treatment of fractures through joints and should serve to simplify the care of such injuries.

Blood Transfusion.—Lester J. Unger (*Canadian Practitioner and Review,* October, 1916) states that there are two general methods in use: 1. That which utilizes the whole unmodified blood. 2. That in which the blood is altered by the use of anticoagulants such as sodium citrate. The latter has the advantage of providing blood which can be stored and used in emergencies or transported as desired. But it has two disadvantages: 1. The alteration of the coagulation time of the recipient's blood, and, 2, the danger of causing high temperature and chills. The first method is free from these objections and if performed with the author's apparatus requires no special skill and is very simple. In a series of eighty-five transfusions no chills were produced and only eight cases showed fever following the transfusion. In sixty-one per cent. of the cases there was improvement or clinical cure and the transfusion was life saving in twenty-two per cent. of the cases. Life was saved in cases of postoperative hemorrhage, hemorrhage of the newborn, intraabdominal bleeding, duodenal ulcers, and ruptured ectopic gestation sacs.

Aftercare in Pulmonary Tuberculosis.—P. C. Varrier-Jones (*Lancet,* September 30, 1916) points out with emphasis that many of the ultimate failures encountered in the treatment of pulmonary tuberculosis are due to the lack of facilities for the proper aftercare of the patients following their discharge from sanatoriums. A patient may have been able to do a moderate amount of work while in the sanatorium where he received adequate nourishment. Then he is discharged and is forced at once to earn a living for himself and possibly also for a family. The strain of the increased work and the longer hours, coupled with an almost certainly inadequate food supply, is often enough to carry him down again. From such relapses the patients often pass into a state of chronic progressive tuberculosis, instead of becoming useful citizens. What is seriously needed is some means whereby such persons may return slowly to full working capacity, while receiving sufficient financial aid to eke out their earnings to a point sufficient to provide good food and favorable living conditions. Such a form of aid would cost less in the end than the present plan of letting these patients relapse and become public charges in a few months.

Duodenal Alimentation.—Joseph W. Larimore (*Journal of the Missouri State Medical Association,* September, 1916) considers that the duodenal tube is our most efficient means of continuing artificial ingestion. While the tube is in position the patient must lie either on the right side or on the back—never on the left side. Cocainization of the throat and esophagus is unnecessary and feeding progresses better and patients are more comfortable if the tube is allowed to pass into the third part of the duodenum or even into the jejunum. The tube is known to be in the duodenum when yellow bile can be persistently aspirated. Feeding is accomplished by three methods—slow injection, gravity flow, and the drop method. Laxatives may be given through the tube.

Use of Insecticides against Lice.—A. Bacot (*Brit. Med. Jour.,* September 30, 1916) conducted many carefully controlled experiments upon man to discover a practical means of preventing the spread of lice among the troops. A large number of drugs and preparations were tried; the only one which proved of value and which was at the same time cheap and harmless was found to be crude liquid phenol. It was found that this could be made into an emulsion with soft soap in the proportion of about fifty per cent. of each and the underwear of the men saturated with this mixture after its dilution to five per cent. with warm water. The efficiency of such an impregnation declined so that after about six days the garment required fresh impregnation.

Puerperal Septicemia Cured by Autogenous Vaccine.—William Grier (*Brit. Med. Jour.,* September 30, 1916), after two doses of an antistreptococcic serum and one of a streptococcic vaccine, administered an autogenous vaccine prepared from the patient's organisms and given on the sixteenth day of her illness. The initial dose contained twenty-five million organisms. This vaccine was repeated at intervals of two or three days, and the dose was finally raised to seventy-five million organisms. Improvement began in a few days after the beginning of this treatment and progressed favorably to complete recovery. The organism isolated from the patient's blood was a diplostreptococcus which conformed to the characteristics of the organism found by Mair in scarlet fever.

Hexamine in Aural Suppuration and Meningitis.—Douglas Guthrie (*Brit. Med. Jour.,* September 30, 1916) noted that hexamethylenamine appeared in the discharges from the ear and in the spinal fluid, and therefore sought to make use of it as a means of treating aural suppuration by douching the ear with an acid solution to liberate the formaldehyde. He gave the drug, therefore, in large doses to each of four cases with chronic otitis media and applied the Rimini-Burnam test to the discharges. He found the secretions in all cases entirely free from either hexamine or formaldehyde, although the latter was present in the urine in effective amounts. Similar results were obtained with the spinal fluid in two cases of meningitis, in one of which no trace of the drug could be detected even after a single dose of nearly four grams of the drug.

Recent Progress in the Treatment of Uterine Cancer.—J. H. Jacobson (*Journal A. M. A.*, October 21, 1916) draws the conclusion from his own experience and a critical analysis of the results of others that the best results are obtained from the early radical abdominal operation in early or operable cases. Since there are decided differences in the malignancy of the various types of uterine cancer the type should be determined whenever it is possible to do so. The use of radium, x ray, and Percy's operation should be restricted to the extensive cases until their superiority over surgical measures has been demonstrated. Finally, the combination of radical operation with postoperative radiotherapy probably offers the best results of all the methods available at present.

Rate of Absorption of Various Digitalis Preparations.—C. C. Haskell, C. S. McCants, and F. P. Gardner (*Archives of Internal Medicine*, August, 1916) point out that certain experimental observations have strongly indicated that the presence of alcohol in any drug preparations used tends to retard the absorption of these drugs from the alimentary tract or when injected subcutaneously. They sought to ascertain whether an appreciable influence of this nature was exerted in the case of digitalis preparations. Their experiments were performed on dogs and cats. Unexpectedly it was found that the official tincture of digitalis is absorbed more rapidly from the gastrointestinal tract of cats than is an infusion made from the same leaf. Three special digitalis preparations, viz., digipuratum, digalen, and digipoten, were also investigated, but appeared to possess no decided advantage over the official tincture. Digalen was absorbed more rapidly than the tincture, but this advantage is deemed more than offset by the variability in strength, low standard of power, and high cost of this preparation.

Surgical Treatment of Perforated Ulcer of the Stomach.—Abraham O. Wilensky (*Annals of Surgery*, October, 1916) draws attention to the fact that in a few cases of perforated ulcer of the stomach jejunostomy will be indicated. When the ulcer which has perforated is high up near the cardia in an inaccessible location, or in those conceivable cases when it is impossible to find the perforation, or the condition of the patient does not permit an extended search, the indication is to exclude and put at rest the entire stomach and duodenum, and this is best done by jejunostomy and jejunal feeding. Cases are also met in which large perforating ulcers are found on or near the greater curvature, in the general region in which it is proper to make a gastroenteric anastomosis, and in which the presence of extensive adhesions precludes the possibility of making a gastroenterostomy. In such cases the condition of the patient and the local limitations prevent the excision of the ulcer area. In these cases, jejunostomy is indicated, and it practically becomes a matter of necessity. Excision of the ulcer area in the presence of an acute perforation is a dangerous procedure, and is rarely, if ever, indicated. It would find its chief indication in acute perforations of carcinomatous ulcers.

Simple Procedure for Nasal Bleeding.—William Lapat (*Journal A. M. A.*, October 14, 1916) reports that spontaneous recurrent epistaxis is usually due to ulceration over capillaries or a vessel in the anterior nares, but at times it is difficult to locate the precise area from which the hemorrhage comes. This difficulty may be overcome by an application of epinephrine to the anterior portion of the septum. This blanches the whole mucosa except at the spots which give rise to the bleeding. These then stand out clearly against the pale surface as red, circular areas. The treatment is cauterization of these spots with ninety per cent. trichloracetic acid.

Prevention of Gallstones.—Thomas A. Watson (*Brit. Med. Jour.*, September 30, 1916) concludes that the essential feature in the prevention of the formation of calculi in either the urinary or the gallbladder, is by keeping the viscus properly emptied. In the case of the gallbladder this can be accomplished readily once each day by massaging the region of the organ each morning with the round end of a twelve pound dumb-bell. The emptying of the bladder, which is full in the early morning can be heard as a gurgling sound and its result is the production of a free movement of the bowels in about half an hour. This treatment should never be used during an attack of biliary colic, but is an effective prophylactic.

Operating upon Ulcers of Stomach by the Intercoloepiploic Route. — B. Sherwood Dunn (*American Journal of Surgery*, October, 1916) says that gastric ulcers repair best if they are resected. Resection is easy if the ulcer is located at the level of the pylorus. It is more delicate and difficult if they occur upon the lesser curvature or posterior gastric face, and especially if found high up near the cardiac opening. By his new route it is comparatively easy to find the hidden ulcer, and it is a boon to the surgeon when inflammatory adhesions must be separated. The ulcer once liberated may be resected, but if the surrounding surfaces are much inflamed, it is better to perform a partial gastrectomy, which will be found less grave and more efficacious.

Spinal Anesthesia.—Percival P. Cole (*Lancet*, October 7, 1916), using the Billon solution of ten per cent. of stovaine in sodium chloride solution, has secured ideal results from the following plan of procedure. Half to one hour before operation a dose of morphine and atropine is given and the patient is told that consciousness will not actually be lost, but that there will be drowsiness and absence of sensation. The ears are then plugged with cotton and the eyes bandaged. The stovaine is then injected intraspinally, and the patient placed on the operating table with the feet elevated. During the operation all noise is avoided and there is no talking. No tests are made of the height or degree of the anesthesia, but the patient's face is watched while the towels are being clipped to the skin. This plan gives perfect anesthesia, perfect muscular relaxation, and is not followed by aftersymptoms. It is specially valuable in avoiding shock and is indicated particularly in acute abdominal conditions and in cases in which a general inhalation anesthesia would be contraindicated.

Carbon Tetrachloride in the Treatment of Wounds.—L. MacAuliffe (*Bulletin de l'Académie de médecine,* September 5, 1916) recommends carbon tetrachloride as a satisfactory and inexpensive substitute for benzine, ether, chloroform, or alcohol in removing fatty substances from the skin around wounds. Though it does not mix with water, a few drops of it placed on the skin greatly facilitates the removal of greasy material with hot water when the latter is rubbed over it. Carbon tetrachloride is neutral and stable under ordinary conditions, is slightly less volatile even than chloroform, more strongly antiseptic than the latter, and practically devoid of danger from inflammability. Its ethereal odor, by some deemed unpleasant, is easily disguised by dissolving a little menthol in it. In the author's experience, one litre of carbon tetrachloride sufficed in the cleansing of over 300 wounds.

Röntgenotherapy in Hypertrophy of the Thymus Gland.—Philip H. Cook (*Boston Medical and Surgical Journal,* October 5, 1916) reports three cases of enlarged thymus in small children, which were affected favorably by x ray treatment. In conclusion, he quotes the following deductions of Lange, which he endorses. Röntgen irradiation of the thymus produces artificial involution of the gland. X ray therapy is the method of choice in cases of enlarged thymus in children, whether the symptoms be mild or urgent. Urgent cases should receive repeated massive doses. Recurrences due to regeneration of the gland are to be watched for and controlled by further treatment. Children whose physical or mental development is retarded should, if suspicion is directed toward the thymus, receive tentative x ray treatment even though a positive diagnosis cannot be established. X ray therapy as a precautionary measure, or preoperative treatment may enable children of the so called lymphatic type to withstand intercurrent disease or anesthetics, which would otherwise prove fatal. Preoperative exposure of older children and adults, where there is a suspicion of enlarged thymus, might lessen operative mortality. Routine preoperative x ray treatment in cases of hyperthyroidism should be resorted to with a view to lessening operative mortality. X ray exposure of the thymus gland has proved harmless, whether in normal or abnormal subjects; a therapeutic test with the x ray is, therefore, always permissible.

Vaccine Therapy in Septic Wounds.—Kenneth Goadby (*Lancet,* September 30, 1916) concludes from an investigation of the natural history of septic wounds, that intelligent vaccine therapy may be employed with the hope of increasing resistance to disease. Vaccines will diminish the general constitutional reaction following the surgical manipulation of the infected wound, and will also prevent or reduce the extension of the bacterial invasion in the vicinity of the wound. They further increase the power of tissue regeneration in the parts affected. Since military wounds are apt to contain anaerobic organisms such as Bacillus aerogenes capsulatus, Bacillus perfringens, and Hibler's bacillus, and since the activity of these depends to a large extent upon a symbiosis with common aerobes, efforts should be made to check the activity of the latter. Polyvalent vaccines should be kept on hand, prepared from strains of organisms isolated from infected wounds, and used at once in all septic cases as soon as they come under treatment. The initial dose of such a mixed vaccine should contain 5,000,000 sensitized, polyvalent streptococci and 10,000,000 proteus. Where there is gas gangrene the mixed vaccine should contain ten million each of streptococci, proteus, and Bacillus lactis aerogenes. The injection should be repeated on the third day and the dose of the organisms other than streptococcus doubled. By that time an autogenous vaccine can have been prepared and may be substituted if necessary. If the stock vaccine is giving good results it may be continued. In addition to the use of vaccines, the general methods of surgery should be carried out.

Celluloid in Plastic Surgery.—Charles Higgens (*Lancet,* October 7, 1916), after trying paraffin and other suggested substances for the plastic restoration of tissue defects, finally adopted a solution of celluloid as the means which gave the best results. The celluloid was used either in solution in acetone or in the form of a secret preparation of dissolved celluloid, the latter being the more satisfactory. Through a small incision beyond its limits the scar tissue was separated from its attachments to the underlying parts and the celluloid was injected slowly and continuously from a strong syringe with a screw attachment to drive out the semifluid mass. Enough was always injected to raise the scar slightly above the neighboring skin; the syringe was then withdrawn and the scar smoothed down by manipulation to the level of the surrounding part and the incision closed with collodion. Celluloid plates were also found serviceable where the fluid preparation could not be employed.

Immune Human Serum in Acute Poliomyelitis.—C. W. Wells (*Journal A. M. A.,* October 21, 1916) believes that from an analysis of the facts this method of treatment is based upon the principles of immunity, but he contends that since the lesions are not limited to the central nervous system, and since the nerve lesions are essentially of the vascular areas, it is rational to administer the serum intravenously or both intravenously and intraspinally. The intravenous dose should be from fifty to one hundred mils daily, and more if obtainable. Each intravenous injection should be followed by lumbar puncture and the withdrawal of some spinal fluid both to relieve the pressure and to promote the circulation through the spinal bloodvessels. In small infants and children it may be necessary to give the serum intramuscularly on account of the difficulty of entering the veins. This plan of combined treatment was followed by the author in fifteen cases and in all there were prompt beneficial effects produced, though these were only transitory at times and four of the cases died. The beneficial effects were more pronounced following the intravenous than the intraspinal injections and no ill effects followed either. The earlier in the course of the disease that the treatment was begun, the better were the results, and serum obtained from persons who had had the disease many years before was less effective than that obtained from more recent cases.

Treatment of Eclampsia.—J. Fleming Goodchild (*Canada Lancet,* October, 1916) advises that at the first signs of danger there be given the imperial drink in large quantities. This is merely the well known cream of tartar and lemon solution and to this may be added sodium acetate one dram to the quart. If the urine does not become normal in amount and findings after a fair trial then active treatment should be instituted with a dose of calomel three grains and compound jalap powder thirty grains. If the bowels are not moved in a few hours then two drops of croton oil should be given in sugar, olive oil, or butter. Ether or chloroform is then given and manual dilatation performed, version done, and the fetus delivered. This usually takes one hour. When the third stage of labor is over a solution made of sodium acetate and sodium chloride one dram of each to the pint is injected under each breast and the patient is put in a hot pack. A fresh pack is used every twenty minutes until there is free perspiration. If the patient is still restless there may be given either by mouth or by rectum thirty grains of potassium bromide with twenty grains of chloral hydrate every two hours. If the patient cannot swallow obviously this must be given by rectum.

Sodium Cacodylate, Its Antiluetic Value in Large Intravenous Doses.—William F. Bernart (*Medical Standard,* October, 1916) is of the opinion that this drug in large doses is of considerable value in the treatment of syphilis, but by no means the equal of our newer remedies. It has an inhibitory action on the spirochetes, but this action is slight even in large doses. It can be classed as a valuable adjuvant in the treatment of syphilis, and can be administered in moderate doses to patients who show idiosyncrasies to the use of the newer arsenicals and along with a mercurial medication it assists in the production of better results. Its only objection is the production of a garlic tainted breath.

Treatment of Tragic Forms of Ruptured Ectopic Gestation Sacs by Vaginal Section and Clamping.—W. Wayne Babcock (*American Journal of Obstetrics,* August, 1916) points out that there are certain tragic cases of rupture in extrauterine gestation in which death usually occurs unless hemorrhage is controlled surgically. Patients with this condition suffer shock not only through loss of blood, but through a blood pressure lowering reflex awakened by the peculiar irritant action of the blood upon the peritoneum. Often the additional shock of an abdominal section determines the patient's death in such cases. To avoid this, Babcock recommends in all alarming cases the following procedure, which he employed in twenty-four instances, with recovery in every case: Under spinal or light ether anesthesia after the usual vaginal preparation and introduction of a weighted vaginal speculum, the cervix is pulled downward and forward, and the cul-de-sac of Douglas opened behind the cervix in the midline by thrusting through a pair of sharp pointed scissors toward the posterior uterine wall. The scissors having been opened and withdrawn, the incision is widely enlarged by traction after insertion of both index fingers through it. Two fingers are at once introduced into the cul-de-sac, the diseased tube located, thoroughly isolated, and pulled down into the vagina, along with the ovary, and a clamp applied close to the uterus, thus arresting the bleeding. The tube and ovary distal to the clamp may then be cut away, unless the patient is moribund. A piece of gauze fully occupying the vaginal incision is introduced into the pelvis high enough to isolate the clamp from the intestinal coils. The patient can thus be returned to bed in from three to ten minutes, with little or no increase in the preexisting shock. The clamp is cautiously opened half an inch at the end of forty-eight hours, rotated ninety degrees in each direction, and removed. The gauze is removed on the fourth or fifth day, and usually need not be replaced.

Rest and Exercise in the Treatment of Pulmonary Tuberculosis.—Charles L. Minor (*Medical Record,* October 7, 1916) states that rest lessens circulation and hence toxin absorption, diminishes oxidation, and lowers temperature, so decreasing tissue waste, puts the diseased lung at rest, rests the heart, lessens cough and expectoration, encourages weight gaining, and also puts the mind at rest. Exercise, however, is of great importance in the latter months of a successful cure. When the afternoon temperature is not over 99.5° F. with a slow pulse, exercise should begin with one to five minutes a day, increasing by one to five minutes daily up to three hours on a stretch or eighteen holes of golf. Temperature is the best guide to exercise, 100.6° F. or over indicating absolute rest in bed, while a pulse rate of 100 or over indicates rest. Abundant cough and expectoration, especially blood streaked, contraindicate exercise, as do loss of weight and fatigue on exertion. Exercise begins with sitting up in a chair, then crocheting for women and solitaire for men, progressing to walking, which is the best of all exercises. Automobile riding is forbidden until the patient can walk one half to one hour without ill effect. Minor never discharges a patient as cured until he can walk for three hours over hilly country without undue dyspnea, loss of weight, fatigue, or tachycardia.

Vaccine in Mediastinal Actinomycosis.—W. S. Malcolm (*Brit. Med. Jour.,* October 7, 1916) states that salvarsan, the use of iodides locally or of massive doses of potassium iodide by mouth, have all afforded cures, but there are some cases in which they fail, probably because the drugs are prevented from reaching the infected tissues in effective quantities. Such a case was observed by the author, in which there was pulmonary and mediastinal actinomycosis which had broken externally through the sternum. Weekly injections were given of a vaccine containing two and a half million actinofragments a dose. This was slowly raised to ten million. But constitutional symptoms indicated that this was too large a dose. About five million was finally adopted as a suitable dose and this injection was continued until about fifty had been given. Cure followed before all of the doses had been given, but treatment was continued for safety. Under the injections the discharge soon stopped, the sinuses healed, and the nodules and thickening of the parts disappeared.

Miscellany from Home and Foreign Journals

The Etiology of Epidemic Poliomyelitis.—E. C. Rosenow, E. B. Towne and G. W. Wheeler (*Journal A. M. A.*, Oct. 21, 1916) give this preliminary report as a brief summary of the results of bacteriological and animal inoculation studies made during the recent widespread epidemic of poliomyelitis. The studies showed that a peculiar streptococcus could be isolated from the throats, tonsils, tonsillar abscesses, and the central nervous tissues in cases of infantile paralysis, and that cultures of this streptococcus were capable of producing typical flaccid paralysis in a wide variety of laboratory animals when injected intravenously or intracerebrally. The organism was, in turn, isolated from the tissues of the nervous system of the injected animals while the other tissues of the animals were sterile. Study of the organism itself showed it to be remarkably polymorphous, growing especially in two forms, the one a large, the other an extremely small form which would pass through a Berkefeld filter and produce typical growth in culture media and infection of animals. Both forms were found equally infectious to animals and depending upon the nature of the culture medium used either form could be produced from the other. The organism grew best in aerobic cultures and it was chiefly in the anaerobic ones that the small form predominated. The small form seemed to be the one which was assumed by the organism when in the central nervous system.—John W. Nuzum and Maximilian Herzog (*Ibidem*, October 21, 1916), working independently of the preceding group of investigators, have isolated an organism which is apparently similar to the one just described and have found much the same facts regarding its polymorphism and virulence for animals. They were able to recover it from the mesenteric lymph glands in fatal cases of the disease in man as well as from the tissues from which Rosenow and his associates secured it. They also found that the organism was very resistant to glycerination, retaining its virulence for thirty-five days in material preserved in fifty per cent. glycerin.

Deafness Due to Shells.—I. Ranjard (*Bulletin de l'Académie de médecine*, September 12, 1916) terms "shellitis" (*obusite*) the sum of the organic and functional disturbances brought on by a nearby shell explosion. It is one of the commonest causes of deafness in military practice. Such deafness is organic when the apparatus for mechanical or nervous transmission of sound or the organ of Corti is injured; it is neuropathic when the result of functional inhibition of the centres of auditory sensation or identification. The organic form is associated either with otitis media, labyrinthine concussion, or auditory neuritis. The otitis generally differs little from the common form of otitis media, and is recognized by the same signs: Vibrating tuning fork at the vertex best heard by the ear with greater impairment of hearing; or heard least well among the vowel sounds, but with no great difference between the vowels as a whole; vestibular reflexes unimpaired. Concussion often coexists, causing, when mild, deafness, tinnitus, and vertigo of brief duration; when severe, unconsciousness for several hours and a marked Ménière's syndrome. Deafness, which disappears last, may persist for a month or two, or become permanent. The vestibular reflexes are often impaired in these cases. An evanescent auditory neuritis may account for a temporary inhibition of hearing unaccompanied by signs of labyrinthine involvement. True neuropathic deafness, due to emotional shock, is nearly always accompanied by mutism, is bilateral and complete for all sounds, and is unassociated with vestibular disturbances. These three features are not, however, peculiar to it and may exist in organic deafness. One cannot prove clinically that in a given case deafness is purely neuropathic; but neuropathic deafness can be excluded. Secondary auditory identification is often impaired in concussion cases, the patient having difficulty in understanding articulate sounds. Precise diagnosis of the complex deafness from "shellitis" can be made only with a mathematically exact acoumetre such as the vowel siren of Marage, and is of great importance from the standpoint of treatment, neuropathic deafness being amenable to psychotherapy, while organic deafness can, in most cases, be cured or improved by auditory reeducation by the synthetic vowel method.

Dysentery and Dysenteric Diarrhea. — L. Giroux (*Presse médicale*, September 14, 1916) reports on 150 hospital cases, 117 of mucosanguineous diarrhea, forty of common diarrhea, and three of choleriform diarrhea. The onset was usually abrupt. All but five cases ended in recovery. In all the cases labelled dysentery, a sudden increase in the urinary output proved the most certain and early indication of approaching convalescence. This increase took place before any general or intestinal improvement, the output quickly rising from 500 c. c. a day to 1,000. 2,000, 3,000, and even more. An increased output of chlorides was simultaneously noted, the total daily amount rising to sixteen, twenty, and even twenty-three grams in twenty-four hours. The pulse rate also fell to sixty, fifty, and even forty at this time. In three cases paratyphoid infection was added to the dysenteric manifestations; one of these cases showed dysentery bacilli in the stools and ended fatally. In other instances, dysentery was complicated by such conditions as paroxysmal tachycardia, albuminuria, diaphragmatic pleurisy, general purpura, and Raynaud's syndrome. Antidysenteric serum, employed in all cases in which a diagnosis of dysentery had been made, whether upon a bacteriological or merely clinical basis, proved rather inefficient, even in typical instances of dysentery. On the other hand, emetine in doses of 0.04 gram a day, often gave prompt and striking results, the symptoms improving within forty-eight hours and recovery occurring within five or six days. This confirms the statements of Ravaut and Kronulitzky that many instances of dysentery, apparently bacillary, are really

amebic, and that where both infections exist the ameba play the chief role. In choleriform diarrhea the author combats dehydration and circulatory weakness and finds saline solution containing morphine, given even in the presence of albuminuria, of great value to allay cramps and induce restful sleep.

A Simple Infallible Sign of Death.—Francisco Massana (*Revista de Medicina y Cirugia Practicas,* September 21, 1916) appeals for the widespread use of a sign of death first reported by Lecha Marzo of Granada. It consists of an acid reaction of the tears, blood, and organs coming on immediately after death and may be readily tried by introducing a piece of blue litmus paper for a few moments under the eyelid. This phenomenon is absolutely incompatible with life.

The Enterococcus and Trench Fever.—Thomas Houston and John M. McCloy (*Lancet,* Oct. 7, 1916) give extensive bacteriological studies that reveal a very frequent association between the enterococcus and trench fever and allied conditions. This organism was isolated from the blood, urine, sputum, or the pus of wounds in a large proportion of the cases studied. The conditions for which it seemed responsible, other than the infection of many wounds, were of three types. In the first there was a general septicemia with symptoms closely resembling typhoid fever. The second type comprised cases now known as trench fever. And the third presented symptoms of severe myalgia. In all of these forms the condition was relatively long in duration, but the administration of vaccines made from the enterococcus proved of decided therapeutic value. The pathogenicity of the organism and its etiological relation to the conditions mentioned were proved by its frequent isolation from the blood and other fluids, its opsonic reactions, its specific reaction when used as a vaccine, and its therapeutic effects when similarly employed.

Acute Epidemic Nephritis (Trench Disease).—Umberto Gabbi (*Riforma medica,* September 25, 1916) defines this condition as one probably infectious but noncontagious, with mild fever, head and joint pains, edema of face and extremities, and more or less dyspnea and albuminuria. The etiology is obscure, cold weather not being the cause, as the greatest number of cases occurred in June, while alcoholism, rheumatism, mild scarlet fever, typhoid, and dysentery have been excluded. The character of the urinary findings is that of an infectious nephritis in its glomerulotubular distribution, while toxic nephritis is almost exclusively tubular. Bacteriological examination of the blood, urine, and throat was without definite findings. Uranalysis shows reduced quantity, acid reaction, low specific gravity, albumin three to two per cent., hyaline and granular casts, rarely epithelial casts, very numerous leucocytes, and a number of red cells. Complications are acute uremia in seven per cent. of cases, retinal hemorrhage in acute cases, bilateral parotiditis, herpes, and acute mania in four of 500 cases. The mortality is two per cent., while treatment consists in excluding nitrogenous foods and giving a diet rich in carbohydrates, with complete abstinence from alcohol, and securing rest and warmth. The only medication indicated is theobromine in cases with diminished output of urine.

Diagnosis of Tuberculosis by Tuberculin.—H. A. Ellis (*Lancet,* Oct. 7, 1916) has shown, by careful experiment, that the papillary layer of the skin is the most sensitive in its reaction to tuberculin in infected persons. Employing original P. T. O and Koch's O. T. in full strength and in dilutions of one to ten, one to 100, one to 500, one to 1,000, and one to 10,000, applied by deep scarification, the author found that the character and intensity of the reaction bore a constant relation to the degree and stage of tuberculous involvement, but not to the amount of tissue involved. The reading of the reaction had to be made in conjunction with the clinical phenomena Thus when all dilutions gave negative reactions there was either no tuberculosis or the disease was very far advanced and the patient's resistance had been completely overcome. With reaction to the first and second strengths the patients were either dying or only slightly infected, the decision being clear on clinical examination. When first and second were positive and the third doubtfully so it pointed usually to an active process Positive reactions to the first four strengths were found in the majority of active cases in adults and to the gland cases in children. Cases reacting also to the fifth and sixth dilutions showed a state of hypersensitiveness and were in a dangerous condition of balance between infection and resistance. Most patients, however, did well under proper and careful treatment.

Psychic Vaginismus.—P. H. Williams (*American Journal of Obstetrics,* August, 1916) notes how the term vaginismus has been loosely used and expanded to include even such conditions as painful coitus due to tender masses in the cul-de-sac of Douglas, kraurosis vulvæ, senile vaginitis, etc. The term should be restricted to cases of reflex contraction of the constrictor ani, levator ani, and other muscles. He would divide the cases of vaginismus into: 1. The organic, depending on some ascertainable cause such as a tender myrtiform caruncle, irritable hymen, ulcer or fissure about the vulva or lower vagina; 2, the psychic, in which there is no such lesion about the external genitalia—remembering, however, that from repeated efforts at intercourse a condition of extreme irritability about the introitus may be set up, and that an actual neurosis may result from a very small lesion in the mucosa in a highly neurotic individual. Williams reports two cases of psychic vaginismus in which the causative psychic factors were easily ascertained and a permanent cure obtained without operation. In the first case the impulse causing vaginismus and inhibiting coitus had been conscious at first and imparted through suggestion by another person of pain attending intercourse; examination under codeine, sodium bromide, and anesthesin in warmed albolene locally, showed absence of tenderness or organic lesions. Hypnotic treatment failed, but detailed explanation of her case cured her. In the second case the vaginismus arose from long continued willful suppression of the sexual act through fear of the harmful effects of pregnancy on a tuberculous spine. Persuasion of the patient that her fears were no longer justified overcame the subconscious impulse to inhibit the sexual act.

Fixation of the Sacrum.—E. H. Arnold (*American Journal of Orthopedic Surgery,* October, 1916) believes that all cases of sacroiliac and sacrolumbar disturbances, whether due to disease, faulty posture or trauma, should be operated upon when the mechanical methods of fixation have not secured results. In fixing the sacrolumbar joint he either inserts a transplant on both sides of the spinous processes of the last three lumbar and the first two sacral vertebræ or else follows the Albee method at the same site. In fixing the sacroiliac joint, after having made a trough from the sacrum down to the ilium, he inserts a transplant. He reports eleven operative cases, the results of all being good.

Shortening Long Legs and Lengthening Short Legs.—R. Tunstall Taylor (*American Journal of Orthopedic Surgery,* October, 1916) states that in cases where there is a disproportion of at least three cm. between the length of the lower limbs, but where the limbs are straight and parallel, the shortening or lengthening of a limb may be accomplished by operative measures. For the lengthening of a limb, after having previously divided the adductors, iliotibial band, and hamstrings, he makes half sections of a desired length in the middle third of the femur and then exerting traction fixes the sliding fragments by the use of bone dowels. In the shortening of a limb he does not divide the muscles and tendons, but resects a portion of each half section of bone. Otherwise the technic is the same.

Ascaris Infection.—F. H. Stewart (*Brit. Med. Jour.,* Oct. 7, 1916), from a large number of experiments, has demonstrated that ripe eggs of Ascaris lumbricoides swallowed by rats or mice match, and their larvæ enter the animals' livers by the bile ducts or by boring through the venules of the portal system. In the liver they cause rapid degeneration of the neighboring cells, enter the hepatic vein, and gain access to the lungs. From these they soon pass by way of the air cells into the bronchi and appear in the animals' saliva about eight days after the initial infection. From the mouth they are conveyed by the saliva to articles of human food and lead to infection in man. These common rodents are, therefore, probably the usual intermediate hosts of this parasite and are the agents in its spread.

Significance of Pulse Form.—A. W. Hewlett (*Journal A. M. A.,* October 14, 1916) calls attention to the fact that our knowledge of the size and form of the pulse has not kept pace with that of other characters of the pulse. By means of a plethysmograph enclosing the hand, forearm, and lower arm the author has measured the size of the pulse in normal and abnormal cases. He found the size to vary normally between four tenths and one mil and that an unusually large volume pulse occurred in cases of aortic insufficiency—from one and four tenths to two mils. States of chilliness and warmth produced considerable alterations in the size of the pulse in normal subjects—from 0.26 to 0.96 mil, and a febrile chill greatly reduced the size of the pulse, which returned to normal as the sensation of warmth returned. The latter was probably due to vasoconstriction. The pulse form has also been studied by the author with the aid of the same instrument connected with a Frank recorder. Two main types of pulse form were found. The one showed an abrupt rise and a sustained and slow fall; the other differed in having a more or less abrupt fall. The latter gave the impression of a bounding pulse to the palpating finger. The dicrotic wave in this type of pulse varied from being absent to being very large, but appeared to be of less importance than the initial abrupt fall. Sustained pulses were found most commonly in normal persons or those with high arterial tension, while the pointed type occurred in those with abnormally low pressures and particularly in cases of acute febrile disease. The pointed type of pulse was found to be due to a reflection of the systolic wave backward into the vessels, and not to a rapid outflow through the capillaries. Such a reflection was favored by relaxation of the larger arm arteries and a constriction of the arterioles. The phenomenon could not be explained wholly on this ground, however, but rested in part upon the occurrence of a small or brief systolic output from the heart. The most important bearing of the pointed pulse was in connection with circulatory failure in which it became progressively more and more marked and decreased in size.

Value of the Ambard Quotient in the Estimation of the Renal Function.—Leon Jonas and J. Harold Austin (*American Journal of the Medical Sciences,* October, 1916) arrive at the following conclusions: 1, The Ambard formula in its original form, or as modified by McLean, does not express precisely the law of renal function with respect to the elimination of urea, and this is particularly true as regards the effect of urinary urea concentration. 2, The upper limit of blood urea in nonnephritic and normal subjects under ordinary conditions of diet and life is about 0.35 gram urea per litre of blood. Figures higher than this are, under ordinary conditions of diet, to be considered evidence of impaired renal function. 3, Using McLean's modification of Ambard's formula, it was found that in the great majority of nephritic cases a lowering of the index was accompanied by an elevation of the blood urea above normal limits, 0.35 gram per litre, and that the index afforded no information of diagnostic or prognostic value that could not be as readily deduced from the blood urea alone. 4, In certain cases the index was found to be lowered when the blood urea was within normal limits. This was especially true in arteriosclerotic cases and in cases with cardiac decompensation, which probably detracts from the clinical value of the index as compared with that of the blood urea rather than the reverse, since it is of importance to distinguish between cases of vascular and renal character. 5, In the determination of the index there is a possibility of error arising from undetected incomplete collection of the urine, which cannot occur in the simple blood urea estimation. 6, The urea index estimated repeatedly in the same subject exhibits wider variations in the normal or nonnephritic subject than in the nephritic. 7, For purposes of ordinary clinical diagnosis and prognosis the estimation of blood urea is preferred.

Proceedings of National and Local Societies

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting Held at the Academy of Medicine, February 21, 1916.

The President, Dr. THOMAS S. SOUTHWORTH, in the Chair.

Vanadium Steel Bone Plates and Tap Screws in Compound Fractures.—This paper was read by Dr. WILLIAM O'NEIL SHERMAN, of Pittsburgh.

Dr. JOHN B. WALKER said that they were indebted to Doctor Sherman for bringing this important subject before them. While the general principles of operation on thirty-one simple fractures were well recognized, there was still some discussion as to the time when the operation should be done. Showing the increase in the number of operations for fracture, he had gone over the slips sent out by the Society for the Advancement of Clinical Research. In the first five months of 1915 there were 360 cases of fracture. Seventy-one of these were fractures of the femur and twenty-nine were compound fractures. In the last seven months there were 752 cases; 173 of these were fractures of the femur and forty-nine were compound fractures. In 1915 there were about 1,100 fractures, 250 of the femur, and seventy-five compound. When they recorded the experience of 1915, they appreciated that there was a great increase over 1910, 1911 and 1912, and they recognized that the profession was alert to the necessity of operation in simple fractures, the necessity in compound fractures was not generally recognized. The men who had had the largest experience found that they could put in plates, but many others doubted the possibility of doing so without danger to the patient.

Doctor Sherman had spoken of the large number of compound fractures reported from the seat of war—fifty per cent. compound fractures. Looking over the report of the American Ambulance, and also that of the English surgeons, they found that plates did well. They had had much experience, and were using plates or some form of internal fixation in many of these cases instead of relying upon plaster.

The question of early operating had not been definitely decided. Doctor Sherman gave a definite time for operation. Certain men, feeling that the compound fractures would give the greatest difficulty in healing, felt the operation ought to be within the first week, as by the end of the seventh day most of the retraction would have taken place.

Doctor Walker began using Lane's screws and plates six years ago, but during the last year and a half he had abandoned them and had been using Doctor Sherman's, and he felt confident that the latter had many advantages over Lane's and that they should be used in practically all cases.

Dr. CHARLES H. PECK expressed some hesitancy in joining in the discussion as in his service at the Roosevelt Hospital there were comparatively few traumatic cases since the ambulance service had been given up, and there were very few acute compound fractures compared with what they used to have. He had looked over the record to 1910, and found that on the second surgical division, there were ninety-one open reductions of fractures of various kinds; among them only twenty-nine cases had been plated; practically none were compound fractures. They were distributed among various bones of the body, the largest number being in bones of the forearm. There were two infected cases—one an infected radius which resulted in delayed union with final good function; the second patient had a fractured femur with multiple injuries, and died from a lung abscess which developed later from thoracic injury and had a slight secondary infection around the plate. The others healed, and there were no cases of recorded nonunion; one humerus had a delayed union, and the plate was removed after several weeks, and ultimately good union occurred. He believed that in fractures in general internal fixation of some sort should be used without question if good reduction could not be obtained and maintained by the closed method. If possible, most surgeons felt that closed reduction should be made under general anesthesia, and if, after careful trial, it was found that reduction could not be maintained, open methods should be instituted.

The speaker again expressed his regret that he could say so little in direct relation to Doctor Sherman's subject, the proper treatment of compound fractures. He wished, however, to refer to the application of these principles which he had seen at Panama in the service of Doctor Herrick, at the Ancon Hospital, in 1913. There they were using technic similar to that laid down by Doctor Sherman—making the incision away from the original wound, and carrying out the lines of treatment which Doctor Sherman advised.

In regard to the vanadium steel plate and tap screws, Doctor Peck said they had adopted that type of screw at Roosevelt Hospital for the last two years, and had practically given up the Lane plate and the aluminum plates formerly used. He joined with Doctor Walker in expressing indebtedness to Doctor Sherman for bringing before the the association this splendid mass of material for the treatment of compound fractures. These fractures should not be left to go on to vicious union which is so difficult to correct later in the case.

Dr. FRED H. ALBEE agreed with Doctor Peck, Doctor Walker, and Doctor Sherman that the vanadium plates and tap screws were preferable to the older, less accurate screws that had been used hitherto. The forcing of a wood screw into the bone did a good deal of tearing. Then, again, the wood screw did not hold so well as the tap screw used by Doctor Sherman, and might produce an amount of compression sufficient to cause the death of the neighboring bone cells followed by their immediate absorption and the loosening

of the screws, thus defeating the very purpose for which they were inserted. The speaker had not had a very large experience in the treatment of fresh compound fractures. A large proportion of those that came under his care were ununited fractures, simple fractures, or old compound fractures where the soft tissues had healed. Reasoning from the repair of bone, he believed that internal fixation was especially indicated in such cases as Doctor Sherman had presented. The laceration of soft tissues, in compound fractures, interfered seriously with the fixation of the fracture, and the constant motion that must occur with an improperly fixed fracture contributed to the progress of infection, if any existed. Pringle, of Glasgow, had tabulated 230 cases of compound fracture, and had arranged them in reference to internal fixation. He had used three methods of fixation—the plate, the wire, and the screw. He had found in his series of cases (about one third treated without internal fixation, and two thirds with fixation) that of those treated with internal fixation 10.8 per cent. came to secondary amputation, whereas only 2.6 came to amputation when he did use internal fixation. He was strongly in favor of internal fixation in compound fractures, necessarily, from his statistics.

In following his report, it was interesting to note that for some time he had practised putting back the fragments of bone, where there had been a compound comminuted fracture—and if it was necessary to take them out in cleaning the wound he put them in a saline solution until they could be replaced. In a number of instances, they were cleaned of dirt and then put back. The fact that under such conditions these bone fragments lived and united to the near fracture fragments, went to prove the usefulness of the bone graft as an internal fixation agent. The resistance of the living bone graft to the infection had not yet been appreciated by the profession. This brought up the subject of whether in certain cases of compound fracture a bone graft could not be used from the end of one fragment in the form of a sliding inlay and employed as a means of fixation in place of metal. The speaker believed that in most cases it was preferable to metal.

A word in respect to silver wire: In the last few months he had been carrying on some experiments as to the trustworthiness—or rather untrustworthiness—of wire, especially of silver wire, and he had been somewhat surprised at the results. In some instances, the ordinary size used in bone work had parted at only ten pounds traction—usually at the twisted knot. On the other hand, he found that heavy kangaroo tendon was very strong and much more to be depended upon; some of the strands tested up to one hundred pounds' traction at the knot. That was very important; if a compound fracture could be held by wire, kangaroo tendon seemed preferable, since it was an absorbable material, very easy to insert, and disappeared in about forty days.

Dr. J. H. Branth said that the Lane plate was one of the greatest advances yet made in bone surgery. By the Lane method, the surgeon cut down to the seat of fracture, cleaned out blood clots, and removed loose splinters of bone. When tendons and muscle tissue were between fragments of bone, they were replaced in proper position for future normal function. The bone fragments were then brought into accurate apposition, which was not difficult, as the patient's muscles were relaxed by anesthesia and the parts were in view. In all fractures, whether transverse or oblique, there was a serrated condition of the fracture surfaces, and by interlocking this assisted in maintaining correct apposition. The periosteum was also drawn as far as possible over the fracture. The Lane plate was laid on parallel with the shaft of the bone, a hole drilled in one end of the fractured bone, and a screw inserted to hold the end of the plate in place. Then the plate was adjusted to overlap the other part of the fractured bone, and the limb was brought into normal position and held steady by assistants. A hole was then drilled for the second screw, and the screw brought home after which the soft parts were carefully adjusted, perhaps with the aid of sutures. All clots were removed, the wound was closed aseptically and covered with gauze, and the limb encased with plaster bandage. It was remarkable what firmness was secured by such a simple procedure. By the treatment described, the fractured surfaces were brought into and kept in accurate apposition, and nature had but little work to do in establishing repair. There was less spasm of the muscles because less irritation, the parts being all in place and no debris or tissue between the fracture surfaces. The speaker was the guest of Mr. Lane in 1905 and again in 1906, and on one occasion the London surgeon showed him a patient who had been admitted to Guy's Hospital suffering from fracture of the femur, upper third, and also from delirium tremens. This man was walking in the yard with a cane five weeks after a Lane operation. The speaker made an x ray examination, himself, which showed the plate in position. When they considered that fracture of the thigh, with complication of delirium tremens, generally meant a fatal issue, this result was remarkable.

Mr. Lane used a sterilized steel plate, two or three inches long with two holes, one on each end. He then used a carpenter's wood screw. The latter had a long neck and the screw end might reach through the bone wall into the marrow, a condition in which the screw would have no firm hold and would act like a peg or nail. Such a screw might slip and spoil the result. During that visit, the speaker saw such a case, and verified the condition then, by personal measurement and x ray examination. Then and there he suggested to Mr. Lane the use of a machine screw with the thread extending up to the head. The hole should be made by a drill to fit the screw. Mr. Lane accepted the suggestion, saying that he would discard the carpenter's screw. Such a machine screw would secure a firmer hold in the bone. They might ask, What became of the metal plate? It remained where it had been fixed; callus would surround the plate, making the union firmer.

A few points in the technic might well be mentioned: The screw should not be much larger than the thickness of the bone wall; the screw should not extend far into the marrow canal, for

this would interfere with the process of repair and increase irritation. Another point: When the screw was brought home, the operator *felt* when it was tight. He then should turn it backward a sixth or a quarter turn. This would reduce the tissue's hold on the screw thread; the bone cells would swell from the presence of the foreign body. The screw might be cast off by a fully developed inflammatory condition. In any event, it seemed probable that the screw *not drawn fully tight* would soon become tight during the process of repair. Applied under proper conditions, it ought not to cause any trouble. Should an abscess and sinus form and the plate be cast off, it was owing to a defect in asepsis, or because some dead debris had been left in the wound. The Lane method of treatment therefore seemed to be ideal. Of course, low vitality, as produced by preexisting conditions, such as diabetes, Bright's disease, syphilis, etc., was a factor to be considered in the prospect of recovery. This subject was discussed in this association some five years ago, and then the speaker described the faults of the carpenter's screw and the advantages of the machine screw (see *Year Book*). The Lane plates as now made seemed faulty because the constricted parts between the screw holes was weak and might break. The first Lane plates were made of a bar of steel, two to three inches long, a half or nine sixteenths of an inch wide, and one sixteenth of an inch thick, with a counterhole sunk at each end; there was no weak spot in such a plate. Vanadium steel would, of course, be stronger. However, the plate was there only to secure immobility between the fracture ends; the plaster roller bandage also contributed to this end until nature had produced callus and a bony union.

Dr. H. M. Silver called attention to one fact that had not been spoken of, the use of Steinman's nail in simple and compound fractures. In his service at Gouverneur's they had had very wonderful results with this nail, passing it through the malleoli, and putting over the wound a gauze pad wet with iodine. These cases were first x rayed, and then the Steinman nail was put through the condyles or through the tuberosity of the tibia in fractures of the femur; if through the tibia, it was put through the malleolus or os calcis, and then they could secure thirty or forty pounds of traction; and it was very simple, even without splints, to keep the fracture in position. He thought that if Doctor Sherman tried the Steinman pin in this way, he would be pleased with it. Doctor Lyle said that they were using it with much satisfaction in France, in bad gunshot wounds. With it they would get their traction at once and not have to wait to put on plates.

Dr. Thomas Darlington had seen something of Doctor Sherman's work, even at the beginning of his own work with a large western steel company, and any one that knew anything of a steel company knew that in a large plant there would naturally be a large number of accidents. When he first became acquainted with Doctor Sherman, there were in some parts of the steel works as high as fifty per cent. of septic cases. In the last few years, this had been reduced to one in 1,000 cases, or 0.1 of one per cent. Perhaps the most remarkable part of his work had been the lessening of the sepsis.

Doctor Sherman first called attention to Doctor Walker's reference as to time of operation. It had been their custom to delay operation in simple and compound fractures, never operating before the eighth or twelfth day, as an immediate operation after the receipt of fracture did much harm, as the traumatized tissue should be given time to react. Regarding the work of Doctor Herrick and Doctor Noland at the Panama Canal, referred to by Doctor Peck, Doctor Sherman cited Doctor Noland as advising him that the Lane plates and screws had been productive of much trouble, and that they had discontinued using them, adopting the Sherman vanadium plate and tap screws, which had produced very satisfactory results. As to Doctor Albee's reference to Pringle's statistics, he did not see how so many cases came to amputation; but it must be borne in mind that the charity patients seen in the services of the large city hospitals were, from the standpoint of resistance, quite different from the steelworker and coal miner, because infections from street wounds were usually virulent, while coke, coal, and iron ore were generally sterile. Regarding kangaroo tendons to hold a fracture in position, it was questionable how long they would withstand muscular spasm, and it was reasonable to assume they would not stand up when steel plates broke and screws pulled out. Doctor Albee's suggestion with reference to the cleaning of pieces of bone and placing them back in the wound, was a good one, and although he had never tried it, he would do so with the hope it would aid in osteogenesis. The "before and after" pictures illustrating the Steinman pin did not reveal a very good correction of the deformities; extension by means of the Hawley table could be applied just as effectively without the Steinman pin.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Thirty-eighth Annual Congress Held at Washington, D. C., May 9, 10, and 11, 1916.

The President, Dr. G. Hudson-Makuen, in the Chair.

The Psychology of Diseases of the Respiratory Tract (President's Address).—Dr. G. Hudson-Makuen, of Philadelphia, remarked that while the specialty of laryngology was dependent upon all the various specialties in medicine, its progress and development depended chiefly upon a knowledge of psychology and its related branch, neurology. Psychotherapy had been practised after a fashion since the beginning of the history of medicine, but it had not kept pace with the other forms, the chief reason for this being that the successful practice of psychotherapy required on the part of the practitioner the profoundest knowledge of both medicine and man, and especially man. Few physicians were mentally and temperamentally capable of practising psychotherapy, and the improved curricula of the schools did not supply the rising generation of specialists with the assistance which they should have.

Since many of the diseases of the respiratory

tract were purely functional and of psychic origin, the laryngologist should be able to distinguish between those of his patients who were psychopaths and neuropaths and those who were suffering from actual organic diseases. He should realize that to treat a purely psychic case by physical measures was not only useless, but in many instances absolutely harmful, and to operate merely for the psychic effect of the operation was exceedingly questionable surgery.

Psychotherapy in the form of education and reeducation should always be used, in addition to the necessary medical and surgical measures, for the relief of disturbed respiratory, phonatory, and articulatory functions. It was not enough to do operations for the correction of disturbed functions without at the same time or immediately thereafter doing something in an educational way to correct the faulty habits which accompanied, either as cause or result, the conditions that they were seeking to modify or cure. An example of the psychophysical habits that arose owing to functional disturbances due to organic lesions was found in the speech of the patient having a cleft palate. When this characteristic speech had developed no amount of adequacy or efficiency of the palate brought about by operative measures could in itself appreciably change or improve the speech, because the subject accepted his old speech as normal.

This principle obtained in all their operations upon the respiratory tract, the object of which was to correct faulty function. Its value was apparent in dealing with disorders of speech, the treatment of which differed not from that of other disorders of the respiratory tract. Formerly, distinguished surgeons operated not alone upon diseased and abnormal structures, but also upon perfectly normal structures, not hesitating to remove cross sections of the tongue and epiglottis, in the hope of curing stammering. To those of the present day this was absurd, for they knew that stammering in the great majority of instances was of psychic and not of physical origin, and to cure the affection psychotherapy was quite as important as physicotherapy. What was true of stammering was also true of the other defects of speech.

As the medical profession had been slow in recognizing that stammering and other defects of speech were largely of psychopathic origin and required for their cure psychotherapeutic measures, so had they been slow in recognizing that many forms of asthma, sore throat, and difficult nasal breathing were of similar origin and required similar treatment.

In no specialty of medicine was the importance of these matters so apparent as in their own, for in no specialty was the psychic element so great a factor in the causation, not only of functional, but of organic disorders as well. It must not be overlooked that faulty methods of breathing, vocalization, and articulation, although at first of psychic origin, frequently resulted in organic diseases which could be differentiated from diseases having purely physical bases.

A study of the psychological phenomena as they appeared was merely a study of reactions to environment; or, in other words, a study of what had been called mentation, behavior, and personality. The new psychology, therefore, taught them not merely how to treat diseases of special organs, but how to treat the patient himself or the reactions of the patient to particular diseases. A knowledge of this psychology would broaden the scope of their work, and would tend to make a medical education absolutely necessary to those desiring to practise the various forms of the healing art; but so long as physicians generally disregarded this fact, so long should they have nonmedical practitioners, such as Christian scientists, hydropaths, and all the others of their kind, actually invading their field of practice.

Sore Throat Clinically Considered.—Dr. Samuel Johnston, of Baltimore, said that in the clinical study of sore throat they should scan the physiognomy of the patient, mark well any changes in the voice tones, and note the odor of the breath before entering into a more detailed examination of the case. Among the conditions causing changes of the voice might be mentioned paralysis of the soft palate, defects in the conformation of the palatine arch, swollen tonsils, benign and malignant growth in the nasopharynx, laryngeal inflammations, paralyses, etc. The odor of the breath might call attention to such conditions as uremic poisoning, pulmonary gangrene, ozena, necrosis of the nasal bones, etc. The need of careful inspection of the lips, gums, teeth, tongue, palate, pharynx, nasopharynx, lingual tonsils, epiglottis, and larynx was emphasized.

In examining the nasopharynx an ulcer, usually of an infectious nature, was found when least suspected, and in infectious diseases sore throat was by no means uncommon.

The speaker's experience had proved that diseases of these regions differed in no way from similar pathological changes in other parts of the body, and they should receive the same therapeutic and surgical treatment. Conservative and mild measures, however, should be the rule.

Diagnosis and Management of Vasomotor Disturbances of the Upper Air Passages.—Dr. J. L. Goodale, of Boston, recalled that in a large proportion of vasomotor diseases of the upper air passages the disturbances were dependent upon the entrance of a foreign proteid into the system. The method of entrance might be through contact of the proteid in question with the mucous membranes of the respiratory or of the gastrointestinal tract, by inhalation or ingestion, respectively. Foreign proteins might perhaps also develop in or upon these mucous membranes through autolysis of pathogenic or saphrophytic bacteria. The application of the skin test to these conditions was of diagnostic value when employed with a recognition of the phylogenetic relationships of animals and plants as determined by studies in serobiology.

Proteid material for testing should be prepared both from the keratin and serums of domestic animals, from the pollen of the chief varieties of hay fever, and from the various articles of food which entered commonly into the diet. Bacterial proteids derived from the various invaders of the respiratory tract should be available, either in solution or in the soluble form.

When the skin reactions to the various classes of proteins had been determined, the management of cases would depend largely upon the relative preponderance of the local reactions in relation to the clinical history. If the cause was found to be seasonal, as in hay fever, immunizing treatment by injection of pollen extracts was likely to prove of service. The sensitization returned during the following winter, and treatment must probably be repeated annually. If the cause was perennial and was due to inhalation of foreign proteids, it was wiser to avoid the cause rather than seek to effect a cure by immunization. If the disturbing proteid entered into the ordinary articles of diet, a tolerance might be gradually established by feeding the substance in progressively increasing doses. Disturbances of bacterial origin had not yet been sufficiently studied to enable the formulation of a definite plan of treatment, but the results of these investigations confirmed their present methods of treatment, and emphasized the importance of draining regions which could retain the products of bacterial activity. Septic foci should be removed. Vaccine therapy was likely in such anaphylactic cases to be more accurately guided than in the ordinary patient.

Dr. JOHN F. BARNHILL, of Indianapolis, wished to ask one question with regard to whether the matter had been brought down to a working basis. For instance, if a patient came to Doctor Goodale, what plan did he adopt for determining what the sensitization might be? Had he come to any conclusions?

Dr. ROBERT LEVY, of Denver, said that they had been very much stimulated by Doctor Goodale's work last year. He would like to ask two questions. First, what was his mode of procedure when they had a multiplicity of sensitizations? He would like to have that explained more at length. And secondly, having determined for a certain subject his sensitizations to a number of proteids or inhalations (he had particular reference to inhalations), what method did he proceed with in the treatment of these patients?

Dr. HANAU W. LOEB, of St. Louis, would like to ask Doctor Goodale to tell if lactate of calcium and calcium chloride salts had, in his experience, had the effect of reducing the sensitization.

Dr. J. L. GOODALE rejoined that if he had read the whole of his paper, all of these questions would have been answered. Answering the first, as to how they proceeded, the best plan was to see whether the symptoms were present throughout the year, or whether they came at a definite time. If seasonal, they were probably due to something in the air; most commonly, pollen. If they might occur at any time during the year they inquired as to whether they stood in relation to colds or conditions of acute infection of the bronchial tubes. If they saw the patient was entirely well throughout the summer and winter, and once in the fall or spring had a severe cold and asthma developed, they could under those circumstances, rule out cases of foods, and also rule out the question of animals; consequently, it was one of these other products. On the other hand, it might not be fully a seasonal infection in that it might come in November or January, or at any time, and in that case he should proceed to investigate with special reference to bacterial proteids, and look for those organisms that they knew might invade the mucous membranes of the upper air tract. Now, if the symptoms were throughout the year, without much influence from season or travel, or various modifying circumstances, he would look for asthmatic animals—especially in the case of children—cats and dogs. Children did not know that cats or dogs troubled them, but they might have asthma entirely due to them. He had a recent letter from a man whose daughter had been the victim of asthma when four or five years old, who looked like a little old woman. It was really pathetic. He found it was due to nothing but the cat, and they kept the cat away. The child had now resumed the bloom of youth and the parents were greatly gratified. That was the manner in which they should proceed. They brought the season, the occurrence, the incidence and mode of development of the symptoms into relation with the patients, and that simplified it very much. The use of lactate of calcium and the chloride had made no material difference.

Angioma of the Larynx.—Dr. EMIL MAYER, of New York, premised that this affection was of very rare occurrence, the speaker having found only forty cases recorded in the world's literature. He presented the history of a woman, aged fifty-two years, who had a history of previous attacks of laryngitis with hemoptysis, and who had a tumor in the larynx on the left side, extending from the left false cord and covering the true cord on that side. The diagnosis of cancer of the larynx had been made by laryngologists who had seen her previously. The patient was admitted to Mount Sinai Hospital, and the speaker asked to report upon her condition, and remove a portion of the growth for diagnosis, if necessary.

(To be continued.)

Letters to the Editors

A CHAIR OF MEDICAL ETHICS.

PHILADELPHIA, *October 18, 1916.*

To the Editors:

I was particularly impressed with the editorial article entitled, Should There Be a Chair of Medical Ethics? which appeared in the NEW YORK MEDICAL JOURNAL for October 14, 1916.

Owing to my connection as founder and director of the scientific departments of five of the large manufacturing houses, I have been behind the scenes in matters medical ever since my graduation from Jefferson Medical College in 1879. And as chairman of important committees, such as that on patents and trademarks of national medical and pharmaceutical societies, I have been brought into personal touch with a great many leading men in both professions. With the exception of my old friend, Dr. N. S. Davis, of Chicago, with whom I was in personal conference during his life, I have yet to meet any physicians or pharmacists, with the possible exception of my old friend, Doctor Squibb, who seemed to grasp the subject from the broad point of view necessary for its true comprehension.

Medicine has been degraded in rank during the past thirty years, largely because of the ethical lapse of its membership. We preach altruism, but, unfortunately, a large proportion of the leaders in the profession practise the most intense egoism.

I hope the suggestion of your editor will bear fruit, and that in time each medical school will have a Chair of Medical Ethics. F. E. STEWART, Ph. D., M. D., Phar. D.

Book Reviews

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

A Manual of Otology for Students and Practitioners. By Charles Edwin Perkins, M. D., F. A. C. S., Professor of Clinical Otology in New York University and Bellevue Hospital Medical College; Associate Aural Surgeon to St. Luke's Hospital, etc. Illustrated with 120 Engravings. Philadelphia and New York: Lea & Febiger, 1916. Pp. vi-445. (Price, $3.)

Notwithstanding the number of manuals before the profession, prepared particularly for the use of students and general practitioners entering this special line of work, the one under review is especially to be commended for the study of aural conditions. The subject matter is arranged according to the following chapter headings: Anatomy and physiology of the ear, examination of the patient, diseases of the external ear, diseases of the membrana tympani, nonsuppurative diseases of the middle ear, acute inflammation of the middle ear, mastoiditis, sinus thrombosis, otitis media purulenta chronica, suppurative diseases of the labyrinth, complications of purulent otitis media, nonsuppurative diseases of the inner ear, general aural diseases, tinnitus aurium. The student or beginning specialist will find this manual helpful in obtaining the necessary groundwork for future study, and even the established specialist will discover many salient points throughout the text. The text is concise and to the point; every word seems to count. The differential diagnosis of similar conditions which might lead to confusion is clearly and succinctly explained. The illustrations are exceptionally good, clear, and instructive. In spite of the high esteem in which we hold this manual, the author's discouragement of the use of vaccine therapy in otitis media purulenta chronica is regretted, for the many successful cases reported, and the possibility of a cure in the one at hand should tend to encourage the liberal use of this method, especially since no harm seems to result from its employment. A few typographical errors are to be found in the manual, but are insignificant.

Diseases of Nutrition and Infant Feeding. By John Lovett Morse, A. M., M. D., Professor of Pediatrics, Harvard Medical School; Visiting Physician at the Children's Hospital; Consulting Physician at the Infants' Hospital and the Floating Hospital, Boston, and Fritz B. Talbot, A. B., M. D., Instructor in Pediatrics, Harvard Medical School; Chief of Children's Medical Department, Massachusetts General Hospital; Physician to Children, Charitable Eye and Ear Infirmary; Consulting Physician at the Lying-In Hospital and at the Floating Hospital, Boston, etc. New York: The Macmillan Company, 1915. Pp. viii-346. (Price, $5.50.)

The purpose of this book, announced in the preface, is to meet "two distinct needs in American pediatric literature—a detailed description of the scientific basis of rational infant feeding, and a description of the method of infant feeding taught in the Harvard Medical School." The latter object, we are led to infer, is deemed almost, if not quite as important as the former. The authors are evidently not unappreciative of the excellence of the principles of infant feeding imparted in the Harvard department of pediatrics under their charge. America will doubtless feel grateful that the gap in literature referred to is now at last filled satisfactorily, and that a vivifying *ex cathedra* presentation has been formulated for the benefit of the flagging pediatric departments outside the Cambridge institution.

The first section of the work deals comprehensively with alimentary physiology and metabolism in the infant, including the bacteriology of the gastrointestinal canal and the variations in the gross and microscopic appearance of the infant's stools. In Section II, on breast feeding, the advisability of avoiding substitution of artificial for natural feeding is duly emphasized, and the fact pointed out that the reason why women do not nurse their babies is that they do not appreciate its importance, frequently because proper advice on the subject from doctors, nurses, and midwives is not received. The chemistry and biology of human milk are dealt with, and the modes of procedure in breast feeding taken up. Section III deals similarly with cow's milk and principles of milk modification for artificial feeding, while in Sections IV and V are described such abnormal states as pyloric spasm, hypertrophic stenosis, digestive disturbances due to various dietetic factors, indigestion with fermentation, infectious diarrhea, constipation, rickets, and scurvy, with their dietetic and drug treatment.

The Bacteriology of Dysentery in Malaya. By Henry Fraser, M. D., Aberd., Director, Institute for Medical Research. Studies from The Institute for Medical Research, Federated Malay States. Singapore: Kelly & Walsh, Ltd., 1916. Pp. 44.

Fraser here presents the results of two rather extensive series of investigations of the flora of bacillary dysentery as that disease is found in Malaya. Some of the more striking results of this study deserve mention. Thus, of a total of 819 cases of dysentery, 249 were of amebic and 570 of bacillary origin. In only two amebic cases were dysentery bacilli found. Great difficulty was encountered in the isolation of dysentery organisms from the stools, and only about forty per cent. of the cases gave positive results. The Shiga type was found in only one case in nine, the remainder being due to mannite-fermenting organisms. Study of the organisms themselves showed that there were but two types: One the Shiga type which did not ferment mannite, and the other, mannite fermenters which included the organisms of Flexner, of Hiss, of Russell, and of Strong. The work is likely to be of relatively little interest to clinicians, except that suggestive therapeutic results were obtained from the use of a vaccine, but it should prove of great interest to bacteriologists, especially to those who are studying dysentery.

The Panama Canal and Commerce. By Emory R. Johnson, Ph. D., Sc. D., Professor of Transportation and Commerce, University of Pennsylvania; Members Isthmian Canal Commission, 1899-1904; Special Commissioner on Panama Canal Traffic and Tolls, 1911-1913. Illustrated. New York and London: D. Appleton & Co., 1916. Pp. 296. (Price, $2.)

The facts that Doctor Johnson was a member of the Isthmian Canal Commission from 1899 to 1904, and also acted as special commissioner on Panama Canal traffic and tolls from 1911 to 1913, make him eminently qualified to write on the commercial aspects of the canal. To any one who is interested in transportation and trade, particularly in their relationship to the conditions existing prior to the opening of the canal and the changes which have taken place since it has become the great highway of commerce, the book is filled with interesting data.

Doctor Johnson gives us the reasons why the canal was built; not only because of naval considerations, but also because of the development of the Pacific Coast States and the growth of intercoastal trade by rail and water routes. To those who know the cost of transportation, the saving of 8,000 miles between New York and San Francisco, or 9,000 miles between New Orleans and San Francisco appeals most strongly.

The French Canal Company endeavored to build a canal largely for the reason that they thought it would be a good financial investment, like the Suez Canal, but they failed in their undertaking—not through lack of industry or oversight, but because of sanitary problems which were then insoluble.

After their failure the United States undertook the work for the reasons mentioned, and they were particularly stimulated thereto because of the rapid economical development of the west, which occurred about 1900. Doctor Johnson has reviewed at length the distances which are saved by the building of the canal; has given us detailed information of the comparative cost of freight by the old routes through the Straits of Magellan, the Panama route, and the Tehuantepec route, with those since the canal has been opened to commerce. He has also shown how trade routes have altered and commerce has been stimulated between the United States and the South American and Central American countries; and gives us detailed information which is very valuable to the shipping trade as to why the canal must continue to be the main avenue of traffic between the Atlantic and Pacific coasts. He discusses at length the effect which the canal will have on the development of the American marine, and Europe's in-

terest in the canal. A chapter is devoted to the competition which undoubtedly will ensue between the Suez and Panama canals, which proves that certain trade routes will be favored by one, while others will be favored by its rivals.

In all his discussions he shows himself familiar with convincing facts and figures. It is interesting to note that one of the great determining factors in favoring the canal route over others is the cost of fuel, which can be laid down so cheaply at the Atlantic end of the canal. It is well known that coal on the Pacific Coast is almost unobtainable and consequently exceedingly expensive. The fact that vessels passing through the canal can coal so cheaply will undoubtedly determine a great deal of shipping by this route which would otherwise go via the Straits of Magellan.

One chapter is devoted to the tonnage rules governing ships passing through the Panama Canal. A knowledge of these rules seems essential to all commercial marine organizations and the shipping interests which anticipate using this international means of communication.

The last chapter is devoted to the administrative organization of the canal, and shows the efficiency and thoroughness which characterized the officials in charge of this work. To all those concerned with transportation and trade with Central and South America the book is of great interest and real value.

Interclinical Notes

Some years ago, a certain medical after dinner speaker made himself famous by stating that now there were specialists for every area of the body, "except perhaps the umbilicus; I beg pardon, my friends, I was forgetting the staffs of the naval hospitals." The reproach has been removed at last by the publication of a 690 page volume on the umbilicus by Dr. Thomas Stephen Cullen, of Johns Hopkins University.

* * *

We consider as very good news the announcement in the *Outlook* for November 1st, that beginning with the first January issue in 1917, that periodical is to be practically doubled in size; also that although illustration will be better, it will remain, as heretofore, a servant and not a master of the text. Part of the blame for our wretched mental laxity may doubtless be attributed to too many pictures. A certain amount of healthful effort is required to understand a line of text, but anybody seven Binet-Simon years of age can comprehend a picture.

* * *

That *Commerce and Finance* has found it advisable to add a literary supplement to its columns of figures and dollar marks, is, we hope, a sign of the times. If the presumably commercially minded readers of this excellent journal found it dry without a little touch of culture, it is a good sign. Part of the supplement to the issue for October 23d is devoted to an article by Simeon Strunsky, of the *Evening Post*, on Ice Cream, Cigarettes, and American Youth. We commend this essay highly to those of our own readers who may have overlooked it, with its delicate sarcasm and masked indignation.

* * *

Like other people who have given thought to the matter, we have sometimes had our doubts of the value of Latin and Greek as preliminary studies for the man who aspires to be a writer of English; then we find some ludicrous slip by a nonclassical student which recalls us to the classical ranks. The author of a new book on eugenics which ought to prove a useful addition to the average man's library, holds forth in Chapter I somewhat as follows: "The young woman, married to a man with disease in his blood, begins her wedded life, young, enthusiastic, ambitious, *virile* (our italics), etc." The author is so pleased with this adjective that he repeats it a few lines further on. After an operation, the young wife is no longer the same *virile* and ambitious woman. One year of Latin would save a writer from applying to a woman with approval an epithet which connotes about every quality which men dislike in the other sex.

Meetings of Local Medical Societies

MONDAY, *November 6th.*—German Medical Society of the City of New York; Clinical Society of the New York Polyclinic Medical School and Hospital; West Side Physicians' Economic League; Utica Medical Library Association; Brooklyn Hospital Club; Niagara Falls Academy of Medicine; Hornell Medical and Surgical Association.

TUESDAY, *November 7th.*—New York Academy of Medicine (Section in Dermatology); New York Neurological Society; Amsterdam City Medical Society; Lockport Academy of Medicine; Society of Alumni of Lebanon Hospital, New York; Syracuse Academy of Medicine; Buffalo Academy of Medicine; Ogdensburgh Medical Association; Oswego Academy of Medicine; Medical Association of Troy and Vicinity; Medical Society of the County of Yates.

WEDNESDAY, *November 8th.*—New York Pathological Society; New York Surgical Society; Alumni Association of the Norwegian Hospital, Brooklyn; Schenectady Academy of Medicine; Medical Society of the Borough of the Bronx; Rochester Academy of Medicine; Richmond County Medical Society.

THURSDAY, *November 9th.*—New York Academy of Medicine (Section in Pediatrics); Physicians' Club of Middletown; West Side Clinical Society, New York; Brooklyn Pathological Society; Blackwell Medical Society of Rochester; Jenkins Medical Association, Yonkers; Buffalo Ophthalmological Club; Jamestown Medical Society; Cayuga County Medical Society (annual); Society of Physicians of Village of Canandaigua.

FRIDAY, *November 10th.*—New York Academy of Medicine (Section in Otology); Society of Ex-Internes of the German Hospital in Brooklyn; Flatbush Medical Society, Brooklyn; Eastern Medical Society of the City of New York; Clinical Society of the German Hospital and Dispensary; Manhattan Dermatological Society.

SATURDAY, *November 11th.*—New York Association of the Medical Reserve Corps of the United States Army (annual).

Official News

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers of the United States Public Health Service for the seven days ending October 25, 1916:

AKIN, C. V., Surgeon. Relieved from duty in plague eradicative measures at New Orleans, La.; will proceed to the Hygienic Laboratory, Washington, D. C.

ANDERSON, T. B. H., Assistant Surgeon. Relieved from duty in studies of rural sanitation; will proceed to Ellis Island Immigration Station, New York.

APPLEWHITE, C. C., Assistant Epidemiologist. Bureau orders dated October 13, 1916, revoked.

CUMMING, H. S., Surgeon. Granted five days' leave of absence from October 30, 1916.

DESAUSSURE, R. L., Assistant Surgeon. Relieved from duty in studies of rural sanitation; will proceed to the Hygienic Laboratory, Washington, D. C.

FOSTER, M. H., Surgeon. Relieved from duty at the Marine Hospital, Stapleton, N. Y.; will proceed to the Hygienic Laboratory, Washington, D. C.

FOX, W. F., Assistant Surgeon. Relieved from duty on Coast Guard cutter *Unalga;* will proceed to New Orleans Quarantine Station; granted ten days' leave of absence en route.

FREEMAN, A. W., Epidemiologist. Relieved from duty in investigations of poliomyelitis in New York; will return to station at Cincinnati, Ohio.

GALLOWAY, T. C., Jr., Assistant Surgeon. Relieved from duty at the Marine Hospital, San Francisco, Cal.; will proceed to Laredo, Tex., for duty in connection with the prevention of the introduction of typhus fever from Mexico.

Gardner, C. H., Surgeon. Bureau telegram dated October 3, 1916, amended to grant nine days' leave of absence from October 8, 1916.

Hurley, J. R., Passed Assistant Surgeon. Ordered to make a sanitary inspection of the steamer *Majestic* at Washington, D. C.

Knight, C. P., Passed Assistant Surgeon. Relieved from duty at Pensacola, Fla., Quarantine Station; will proceed to the Hygienic Laboratory, Washington, D. C.

Lombard, M. S., Assistant Surgeon. Relieved from duty in plague eradicative measures at New Orleans, La.; will proceed to the Hygienic Laboratory, Washington, D. C.

Miller, K. E., Assistant Surgeon. Relieved from duty in studies of rural sanitation; will proceed to the Marine Hospital, Chicago, Ill.

Mustard, H. S., Scientific Investigator. Ordered to proceed to Jasper, Ala., for duty in a resurvey of sanitary conditions in Walker County, Ala.

Neill, M. H., Assistant Surgeon. Bureau letter dated September 21, 1916, amended to grant twenty-six days' leave of absence from September 23, 1916.

Parran, Thomas C., Scientific Assistant. Bureau orders dated October 13, 1916, revoked.

Ramus, Carl, Surgeon. Ordered to proceed to Washington, D. C., for conference; thence to proceed to Naples, Italy, via Liverpool and London, England.

Reichard, J. D., Assistant Surgeon. Relieved from duty on Coast Guard cutter *Itasca;* will proceed to Baltimore, Md., Marine Hospital.

Roberts, Norman, Surgeon. Relieved from duty at Philadelphia and Marcus Hook, Pa.; will proceed to the Immigration Station, Ellis Island, New York.

Robertson, H. McG., Surgeon. Relieved from duty at Philadelphia and Marcus Hook, Pa.; will proceed to the Hygienic Laboratory, Washington, D. C.

Robinson, D. E., Surgeon. Relieved from duty at Ellis Island Immigration Station, New York; will proceed to the Hygienic Laboratory, Washington, D. C.

Safford, M. V., Assistant Surgeon. Ordered to proceed to Worcester, Mass., for examination of an alien.

Sayers, R. R., Assistant Surgeon. Relieved from duty in studies of rural sanitation; will proceed to the Hygienic Laboratory, Washington, D. C.

Slaughter, W. H., Assistant Surgeon. Relieved from duty in studies of rural sanitation in Floyd County, Ga.; will proceed to the Marine Hospital, Stapleton, N. Y.

Spencer, H. A., Assistant Surgeon. Relieved from duty at New Orleans Quarantine Station; will proceed to Pensacola, Fla., Quarantine Station.

Stimpson, W. G., Assistant Surgeon General. Will reconvene board for the preparation of questions for examination of applicants for appointment as assistant surgeon at the Marine Hospital, Chicago, Ill., November 6, 1916.

Storrs, H. R., Acting Assistant Surgeon. Will proceed to Seattle, Wash., for instruction in the examination of cholera carriers.

Stout, J. D., Assistant Surgeon. Relieved from duty on Coast Guard cutter *Tampa;* will proceed to Arundel Cove, Md., and report to the commanding officer, Coast Guard cutter *Itasca.*

Townsend, J. G., Assistant Surgeon. Relieved from duty in studies of rural sanitation; will proceed to the Hygienic Laboratory, Washington, D. C.

Treadway, W. L., Assistant Surgeon. Will proceed to Sussex County, Del., for studies of the mental condition of school children.

White, J. H., Senior Surgeon. Ordered to attend the annual meeting of the Southern Medical Association, at Atlanta, Ga., November 13 to 17, 1916.

Williams, L. L., Assistant Surgeon. Relieved from duty at Ellis Island Immigration Station, New York; will proceed to the Hygienic Laboratory, Washington, D. C.

Wynne, R. E., Assistant Surgeon. Relieved from duty in studies of rural sanitation; will proceed to the Marine Hospital, Stapleton, N. Y.

Yarbrough, H. C., Assistant Surgeon. Relieved from duty in studies of rural sanitation; will proceed to the Marine Hospital, Chicago, Ill.

Births, Marriages, and Deaths

Born.

Tileston.—In New Haven, Conn., on Friday, October 13th, to Dr. and Mrs. Wilder Tileston, a son.

Married.

Cutter-Robinson.—In Las Cruces, New Mexico, on Friday, October 6th, Dr. Irving T. Cutter, of Winchester, Mass., and Miss Zula Robinson, of El Paso, Tex.

Flynn-Blake.—In New Haven, Conn., on Tuesday, October 24th, Dr. Charles Thomas Flynn and Miss Josephine Rose Blake.

Hallstead-Smith.—In Flushing, N. Y., on Saturday, October 21st, Dr. Walter C. Hallstead and Miss Jessie Smith.

Jantzen-Doyle.—In Brookline, Mass., on Tuesday, October 31st, Dr. Francis T. Jantzen, of Boston, and Miss Alice M. Doyle.

Kretsinger-Kelley.—In Berkeley, Cal., on Thursday, October 12th, Dr. George Kretsinger and Miss Ethel Kelley.

Oberlander-Tyrrell.—In Somerville, Mass., on Tuesday, October 17th, Dr. George James Oberlander and Miss Jennie Agnes Tyrrell.

Powers-Jordan.—In Brighton, Mass., on Wednesday, October 11th, Dr. Edward P. Powers, of Roxbury, and Miss Alice Ready Jordan.

Ragle-Williams.—In Cambridge, Mass., on Saturday, October 21st, Dr. Benjamin Harrison Ragle and Miss Marguerite O. Williams.

Sheldon-Hewey.—In Brookline, Mass., on Monday, October 9th, Dr. Russell F. Sheldon, of Lynn, and Miss Lura E. Hewey.

Died.

Barney.—In Napa, Cal., on Saturday, October 7th, Dr. Hawley N. Barney, of Richmond, Cal., aged thirty-nine years.

Bomberger.—In Harrisburg, Pa., on Friday, October 6th, Dr. Wayne E. J. Bomberger, aged thirty-five years.

Brewer.—In Salem, Ore., on Thursday, October 12th, Dr. Joseph Henry Brewer, aged sixty-nine years.

Brock.—In Richmond, Va., on Thursday, October 19th, Dr. Charles W. P. Brock, aged eighty-one years.

Burck.—In Frederick, Md., on Friday, October 13th, Dr. Lewis A. Burck, aged fifty-six years.

Coppernoll.—In Newark, N. Y., on Sunday, October 15th, Dr. William J. Coppernoll.

Davis.—In Deerfield, Mass., on Friday, October 20th, Dr. Percy G. Davis, aged forty-nine years.

THE BLOOD AND ITS VESSELS IN EPILEPSY, AND THEIR TREATMENT.

BY THOMAS E. SATTERTHWAITE, M. D., Sc. D., LL. D.,

New York.

Though it has long been known that circulatory derangements are produced by epilepsy, it is only during recent years that they have been found, conversely, to produce epileptic attacks. It is the purpose of this paper to give a brief description of the conditions under which these somewhat reciprocal relationships exist, and to urge that in the treatment of epilepsy attention should more frequently be directed to affections of the blood and its vessels.

Taking up the three great divisions of epilepsy, grand mal, petit mal, and status epilepticus: There is in grand mal, as we know, the tonic spasm, marking the first stage, during which there is contraction of the chest muscles, producing difficult breathing, and consequently embarrassment of the greater and lesser circulations, the latter indicated by a cyanosis of varying degree. In the second or clonic stage, the muscular contractions intermit, and the cyanosis coincidently diminishes. In the third, or comatose stage, while the face continues to be congested, there is no marked cyanosis, but there is apt to be palpitation.

In petit mal, which, as we know, is characterized by epileptic seizure without convulsions, there is often an antecedent feeling of vertigo or faintness, indicative of vascular difficulty.

In status epilepticus, representing the closing scene of epilepsy, as convulsion follows convulsion with increasing frequency up to the end, there is an intensification of the circulatory disturbances.

I omit from consideration Jacksonian epilepsy, where the spasms are usually limited to the muscles of the arm, leg, or neck, consciousness being maintained, because circulatory anomalies are not constant features of the neurosis.

It is quite evident, therefore, that in the three principal varieties of epilepsy circulatory disturbances are among the dominating features.

About half a century ago, an inquiry was made into the cardiovascular symptoms of the seizures by Echeverria (1) of New York. He stated then that cardiac diseases might originate epileptiform convulsions from embolism of the cerebral arteries by means of "migratory clots detached from the valves or cavities of the heart"; but he added in another place: "I lack a sufficient number of facts to establish any causal relation between cardiac disease and epilepsy" (2). In fact, his table of 130 male epileptics showed that there was an associated cardiac disease in only four cases, but not one of the 130 had a normal pulse. Of his 176 female epileptics, the heart was involved in sixteen, but there again, it was not known whether the anomaly was functional or organic (3). In 172, however, the pulse was described as soft, weak, very weak, irregular, feeble, slow, or small. Accepting these figures at their face value, as I feel we should, the evidence shows that epilepsy is so generally associated with some disturbance of the circulation as to constitute a feature of it.

In the same year Hare (4) stated that disorders of nerve centres might produce both epilepsy and cardiac trouble, the latter causing epilepsy, in accordance with well known physiological laws, simply by cutting off the blood supply to the brain. This anemia, he said, might also be due to cardiac drug depressants. These statements indicate that there is a reciprocal relation between cardiovascular affections and epilepsy. It is interesting to note that in a single year two Americans made contributions to the essential character of epilepsy that will have to be recognized by future generations of physicians. In fact, our present knowledge of the affection is due mostly to Americans.

Nine years after Hare's work, Blondeau (5) published seventeen cases of epilepsy, doubtless, I think, under the inspiration of Charcot. They included those of Charcot, Holbertson, and Rosenthal, and among the characteristic features was respiratory embarrassment, usually with palpitation and hemic murmurs. The seizures were preceded by aurae, and followed by unconsciousness and coma. The supposed seat of the cerebral trouble was in the bulb. The inference in these cases was that cerebral anemia produced the seizures.

In 1887, Lemoine (6) went a step further and showed that epilepsy might be controlled to some extent by the use of digitalis and caffeine, which of course improve the cerebral circulation. Alcoholic stimulants also have a similar effect. In these instances of circulatory disturbances there has been little proof of organic heart disease, most authors having failed to find any relation between the two

affections, except incidentally. This point was strengthened by Chadbourne (7), when he published a series of eleven cardiac cases associated with epilepsy, for in them he failed to find any proof of the causal relation between the two.

This idea was still further elaborated by Spratling (8), when he stated that though in his 1,070 cases of epilepsy there was evidence of heart disease in 238, we should not necessarily conclude that the epilepsy was due to heart disease. In many cases the converse was the fact, and he expressed wonder that more epileptics did not die during the seizures, from the forceful damming back of the blood on the heart.

There is no doubt in my mind that heart disease, whether organic or functional, is capable of producing epileptic attacks, but its incidence I believe to be extremely rare. In it the seizure is most likely to be due to cerebral anemia, and from a functional rather than an organic disease. But the anemia is far more likely to be caused by some associated constitutional disease, and such an underlying cause should be recognized and treated.

One of the latest contributions to this matter is by Pritchard (9). He has observed that in epileptic seizures the pulse may be frequent or infrequent, while it is rarely normal. There is usually, he holds, no organic heart disease. Interesting contributions to this subject have also been made by Newton (10) and L. Pearce Clark (11).

In the matter of diagnosis, we must contradistinguish these vascular disturbances from heart block, where there is no unconsciousness; from the seizures of Adams-Stokes disease, where there is the characteristic Cheyne-Stokes respiration and infrequent pulse; and from unconsciousness resulting from cerebral hemorrhage, where there may be more or less prolonged unconsciousness and always some degree of paralysis. We must also differentiate them from cardiac failure due to organic disease. It is here that mistakes are apt to be made. Indeed, I am of the opinion that many, perhaps most of the cases of petit mal, especially the very mild ones, are overlooked by physicians.

From the evidence cited, it is clear that epilepsy evokes circulatory disturbances; but does the converse obtain? Can circulatory anomalies produce epilepsy? We have less evidence on this point, but what we have should be sufficiently convincing. Sachs (12) has recently reported two cases bearing directly on this point. In one, focal epilepsy was produced by enlarged veins in the pia mater, in the other by similar conditions in the dura mater. In the discussion which followed, other prominent neurologists confirmed these views, and a case was cited where the epileptic attacks disappeared after the vascular growth at the base of the brain had been removed by operation.

Though my experience in the treatment of epilepsy has naturally been limited, I have in a long practice seen and treated many cases of petit mal, and feel competent at least to express an intelligent opinion. In reference to the general management of epilepsy, I believe that epileptics should have systematized work, congenial surroundings, and a regulated diet, while treatment by drugs should be directed rather to the underlying systemic condition. Sedatives should be avoided as far as possible. In particular, bromides should be given only to prevent attacks or modify them. According to Pritchard, they are useful in only a little over fifty per cent. Opiates should be avoided except in emergencies (Collins, 13). Rest, isolation, and change of environment I believe also to be helpful. This is prophylaxis as well as treatment. If we except the antiluetic treatment of brain syphilis, operations for depressed fractures, or the removal of such a nevus as may interfere with the cerebral circulation, we should, I hold, in view of what I have said, use more cardiac stimulants than has been the practice heretofore. This treatment is not altogether new, but it has been neglected. Gowers (14), many years ago, advocated the use of nitroglycerin, and the benefits obtained were doubtless due to its action as a heart stimulant.

In one of my cases that has already been published in brief, where there was a total cardiac and respiratory standstill, the patient was restored by alcoholic stimulants with the aid of artificial respiration. In this patient there was complete unconsciousness without spasms, and I classified it as a severe attack of petit mal, to which she had been subject, superinduced by intestinal indigestion. The patient, in convalescing from her seizures, which, by the by, are now steadily decreasing in frequency and severity, passes from her rectum vast quantities of gas. In the intervals between her attacks she has taken cardiac stimulants for years.

In another of my cases of petit mal, where there are so called "fainting spells," without unconsciousness, and lasting only a minute or so, or even less, the attacks seem to have been superinduced by an extensive herpes zoster of the neck, shoulder, and chest, which left the skin so indurated that the subcutaneous nerves became involved, making them intensely painful to the touch. While the local induration was being dissipated by the high frequency current and the therapeutic electric lamp, the use of digitalis, strophanthus, and camphor sustained the feeble pulse until convalescence was established. It may be remembered that Brown-Séquard was the first to discover the causal relation between peripheral nervous irritation and epileptic seizures. This last case was therefore one of Brown-Séquard's epilepsy.

My experiences have indicated to me that under intelligent management petit mal does not usually develop into grand mal; having once made the diagnosis and instituted proper treatment, the chances are that the "fits" will gradually diminish in intensity and become less frequent. Moreover, I believe that the recognition of the importance of treating these vascular phenomena of epilepsy will help us very materially in the treatment of epileptics, especially in cases of petit mal.

In concluding this brief survey of the relation of cardiovascular phenomena to epilepsy, I am led to the following conclusions:

1. Abnormalities of cardiovascular phenomena occur in the vast majority of epileptic seizures.

2. The grosser forms of cardiac disease rarely occur in epilepsy. In fact, they are present in so small a proportion as to indicate that they are accidental rather than determining factors of it.

3. That a cerebral disease or abnormality may produce epilepsy is well established. The evidence shows that removal of enlarged veins or nevoid growths adjacent to the base of the skull has been followed by cessation of the seizure.

4. There is therefore a *reciprocal* relation between circulatory disorders and epilepsy to this extent; that epilepsy causes circulatory disturbances and that abnormalities of blood or vessels cause epilepsy. This reciprocal relation I believe to have been hitherto overlooked.

5. In most forms of epilepsy there is cerebral anemia, and this is relieved effectively by various heart stimulants, the high frequency current, and radiant electric light. The importance of the use of cardiac stimulants in epilepsy, I believe, has not been properly appreciated by the profession.

In a certain number of cases, of course, permanent relief is obtained only by antiluetic treatment or some surgical procedure.

7 EAST EIGHTIETH STREET.

STRYCHNINE AS A TONIC.*

BY WILLIAM FORSYTH MILROY, M. D.,
Omaha.

We have a record of certain Athenians and strangers in that city who "spent their time in nothing else but either to tell or to hear some new thing." We have in our own time certain therapeutists who are like these ancient people, and I wish to record a gentle protest against this custom of theirs. It appears frequently. The mischief lies in discarding proved methods of successful treatment in dangerously severe cases, for the sake of others that are only experimental because they are new and supposedly more scientific. While the ultrascientist seeks a demonstration of truth, he must not forget that his patient is a human being with a life to be saved. In the younger generation of teachers of medicine and therefore, of necessity, in the younger practitioners, we see this spirit of egotism which assumes that the fathers in the profession were in the bonds of gross ignorance. Certainly we rejoice and are proud of recent attainments in therapeutics, but there can be no real progress without the conservation of the valuable things we already possess. I realize that in making these remarks I encounter the risk of being regarded as behind the times—emeritus perhaps—but I hold that a sane conservatism is perfectly consistent both with genuine progress and a sane freedom from accepted principles.

So much by way of preface, because this very idea is one of my two reasons for asking you to think again for a few minutes about the old time remedy, strychnine. My other reason is the fact, as I believe, that the profession as a whole only half appreciates its therapeutic value. Doctors are afraid of it. Few realize what it can accomplish when given in maximum therapeutic doses, and it is of that phase of the subject that I wish especially to speak.

I do not know who first used strychnine in maximum doses, as distinguished from the doses ordinarily employed. The idea was new to me when suggested by the late William Pepper in a paper in one of the journals, about twenty years ago. Pepper recommended it in pulmonary tuberculosis. It is in that disease that I have frequently employed it. Its action is there well illustrated and my remarks are based largely upon its use in that disease. I report the following case as bringing out many of the points I desire to emphasize:

CASE. A married woman, American, twenty-eight years old, came to the dispensary clinic in the summer of 1898 with a violent and very acute attack of phthisis. She had hemoptyses several times a day; aphonia; a violent cough with profuse and foul smelling sputum, loaded with tubercle bacilli; severe night sweats; a temperature ranging from 101° to 104° F. and higher; nausea and vomiting, with inability to digest sufficient food; great prostration and rapid loss of weight; in short, every symptom likely to be met with in a violent attack of this disease. Physical examination located the trouble in the upper part of the right lung. It was my opinion that the woman would not live two months. She lived five years and died of pneumonia. During those years she was under my observation most of the time. I was unable to secure very much modification of her mode of living, which was not favorable. She did not go to bed and continued to perform her household duties to the limit of her strength. She took strychnine and no other medicine. Within a week she showed improvement and by the end of two weeks her condition was materially improved. Soon after the limit of tolerance was reached the hemorrhage ceased, her voice cleared up, the cough greatly diminished, and the stench disappeared from the sputum, there were no more night sweats, the fever was largely gone, the appetite and digestion were restored, and she began to gain in weight. It happened repeatedly that the maximum dose being taken for from two to four weeks, she presented herself complaining of one of the symptoms which had abated. The dose of strychnine was then increased beyond the amount that had previously produced muscular spasm and was found to be well borne. On each of these occasions the recrudescent symptom, whether cough, pain, hemorrhage, or night sweat, again was relieved, thus illustrating both the establishment of tolerance of the drug and the necessity for the use of the maximum dose in order to obtain its full effect.

I have usually administered the drug by mouth, four doses daily. I begin with one thirtieth grain and add one thirtieth to the daily allowance at the end of each five day period until eight thirtieths are being given daily, then reducing the increase to one sixtieth until the limit is reached. With the patient in a hospital under careful observation, it is possible to increase the dose much more rapidly, thereby reaching the maximum earlier. It is convenient to employ a one per cent. solution, but it is not, as a rule, practicable to use hypodermic injection over a long period of time. The maximum dose is indicated by the occurrence of muscular rigidity. The first manifestation of this symptom I have observed most frequently in the posterior muscles of the neck, next in the muscles of the inferior maxilla, and sometimes they appear first in the anterior muscles of the thigh. As soon as this physiological effect of

*Read at the seventeenth annual meeting of the American Therapeutic Society, Detroit, Mich., June 10, 1916.

the drug appears unmistakably the dose is reduced only a little, when the muscular rigidity disappears; it is at this dose that the greatest benefit is obtained.

Naturally the total daily capacity for the drug will vary with individuals. For example, one woman weighing about 120 pounds took three fourths of a grain daily for many months. A man weighing 140 pounds took five sixths of a grain daily for a long period. I have given a woman weighing 110 pounds one grain daily for five days with no toxic effect.

Perhaps some of my readers have employed this remedy for tuberculosis. The results obtained are sometimes almost beyond belief. It is not simply upon my own individual experience that I base my opinion. A number of my pupils have tried it with gratifying results. In August, 1906, I published, in the New York Medical Journal, a short paper upon the treatment of tuberculosis by strychnine, of which *Semaine médicale,* for September 12, 1906, following, contained a translation. The following November I received from Dr. Tomaso Staphani, who was conducting a sanatorium for tuberculous patients in the Swiss Alps, a letter requesting more complete details of the treatment. He said: "I have experimented with the treatment upon a patient with far advanced cachexia with almost complete destruction of the left lung. The results are at present very remarkable, an amelioration of the general state, a diminution of the expectoration, etc." Through the same means a similar statement came to me from a physician in Havana. It is by no means proposed to supplant by strychnine the treatment of tuberculosis as now carried out, by rest, fresh air, and rich food. There is, however, a multitude of cases in which it is impossible to secure sanatorium treatment or any approach to sanatorium conditions at home. I earnestly insist that in such cases, especially of the more acute type, and in sanatoriums, when the disease does not yield promptly, strychnine should be given a trial. I also insist that it has not been properly tried unless it has been administered in maximum doses.

Certain nervous disorders also offer a fruitful field for the use of strychnine in maximum doses. So far as I have been able to discover, the French physicians chiefly have availed themselves of this treatment. P. Hartenberg, in *Presse médicale* for January 25, 1913, tells of his experience. He administers the drug hypodermically, increasing the dose precisely in the manner I have described, to as much as one sixth or one third of a grain, which, he says, may be repeated once or twice in a single day. Under this treatment in simple neurasthenia permanent recovery usually takes place in from ten days to two weeks. He further states: "Other conditions in which strychnine is valuable are spinal and neural affections leading to hypotonia and atrophy, tabes dorsalis, cachexias, convalescence, tuberculous disease, etc."

In the same periodical for March 29, 1913, P. Troisfontaines discusses the use of strychnine in large doses. He says: "The author has given daily doses of one third, one half, and two thirds grain of strychnine without witnessing any untoward effect. The larger the dose, the greater the therapeutic results. This amount may be attained in a few days and only exceptionally gives rise to a sense of mild intoxication with slight headache and muscular rigidity. These promptly disappear if the dose is only slightly diminished." He has used it successfully in syphilitic myelitis and in alcoholism, for long periods, the twenty-four hour amount being one third to five sixths grain. In acute conditions such as marked collapse and lung edema he injects one sixth to one fourth grain, repeating the dose, if required, in three to five hours.

One of the most gratifying therapeutic results I personally have ever witnessed has been in the use of strychnine in pneumonia. There is no more trustworthy sign of approaching trouble in this disease than the appearance of edema in the dependent portion of the unaffected lung. I have observed this edema disappear promptly after the injection of one sixth grain and, recurring after a few hours, again vanish with the injection of strychnine. I have observed this to happen repeatedly in the same case and believe I have seen patients by this means carried over a crisis to recovery.

We have in the college of medicine of our university the beginning of a medical library, now numbering fifteen thousand volumes. With the aid of an efficient librarian I have searched this literature for the purpose of learning what has been said within the last ten years about strychinne. There is hardly a word. Strychnine has been considered a "closed incident." Just one exception I have to mention. Strychnine has long been counted one of the most trustworthy remedies in both acute and chronic heart failure because of the opinion that it increases the work of the heart and that it retards and steadies it. Now come numerous observers to shatter this confident faith. J. H. Newbury,[1] R. C. Cabot,[2] James Mackenzie,[3] Parkinson and Rowlands,[4] and others, from a more or less extensive study, all testify that this idea is wrong. The evidence seems conclusive, and we have to admit either that the benefit we have seemed to derive from this use of the drug is imaginary or else we must account for it in some other way.

The mode of action of strychnine I must mention as concisely as possible. It acts primarily upon the nervous system, including the sympathetic system, probably most strongly upon the medulla and spinal cord. Without discussing the precise mode of action, whatever it may be, it results in a stimulation of the physiological activity of practically the whole body. Admitting that cardiac muscular power and blood pressure are not influenced by strychnine, the fact nevertheless remains that the heart action is influenced favorably in certain conditions. For instance, I know a doctor with a crippled heart which becomes irregular and intermittent, with distressing subjective symptoms, whenever he overtaxes it a little. Invariably a few doses of strychnine restore the action to normal, with disappearance of the unpleasant symptoms. It is difficult to believe that the benefit of its use, so long and by so many observed, is all imaginary. James Mackenzie, to quote his words, suggests that, "strychnine acts probably

[1] *Am. Jour. Med. Sciences,* 1915.
[2] *Trans. Assn. Am. Phys.,* 1904.
[3] *Diseases of the Heart,* 1909.
[4] *Quart. Jour. Med.,* 1913.

upon the nervous system and by producing some exhilaration proves useful in cases in which a temporary exhaustion causes distress."

As to its action in tuberculosis, my conclusions are drawn partly by inference. Pathologists now tell us that almost everybody, at some time in his life, has this disease. Few, relatively speaking, succumb. If the tubercle bacilli are able to secure a foothold in the organism, this happens during a time of lowered opsonic index, and if their growth is checked, this occurs when, through rest and fresh air and nourishing food and favorable surroundings, the opsonic index has been restored. Now, strychnine in full doses, by powerful stimulation of the functional activity of the organism, induces this improved condition. I quote the following from Luciani:[5]

> In close association with the tonic action of the spinal centres is the trophic action which they exert upon other centres and upon the peripheral tissues. We know further that in the central nervous system the normal trophic influence is exerted in the same direction as the physiological conduction of excitation. On interrupting the relations of interdependent groups of nerve cells there is arrest of development, if the growth of parts is still incomplete; secondary atrophy if development is already perfect. In this connection we must confine ourselves to the group of well known phenomena, which show that the spinal nerves and their centres, as well as the centres of the brain, are to some extent capable of profoundly modifying the nutritive condition of other tissues.

Cellular nutrition is not a process of passive absorption. It is an active, vital process which is under the direct control of the nervous system. Therefore the profound stimulation of the nervous system by full doses of strychnine, directly promotes a new and vigorous cell activity of the whole body, thus tending to restore the opsonic index. The nervous disorders to which I have referred as capable of being successfully treated by strychnine, represent conditions of depression. The nervous system still retains its ability to respond to powerful stimulation which the big doses of strychnine supply.

In reference to administration I would add that, though the drug may not be wholly eliminated from the body for as long as eight days, it is mostly gone at the end of twelve hours and therefore the doses must not be too infrequent. It is worth while to mention also that there is no tendency to habit formation, and the largest doses may be abruptly broken off with impunity. Further, I would state that this method of treatment is not dangerous. A perfectly safe margin exists between the first appearance of muscular spasm and a really poisonous dose.

I have by no means attempted to enumerate the many conditions in which ascending doses of strychnine are indicated. I am convinced that it should be given in much larger doses than is customary, and this I hope to encourage.

Standardization of Conditions Affecting Posture.—Henry Ling Taylor (*American Journal of Orthopedic Surgery*, October, 1916) reports some of the work accomplished by the American Posture League, Inc., especially as to seating and footgear.

FINAL CONTROL IN MEDICINE.

By Beverley Robinson, M. D.,
New York.

The late epidemic of infantile paralysis has brought to my mind in a very practical way the fact that today we have no authority we regard as final. To the pure scientist, the laboratory worker, it seems as though his word was law, to be listened to and obeyed first of all; yet we know his knowledge is almost wholly experimental and only some of it will endure, and may be the larger portion will later be shown to be faulty and misleading.

The health board does not lay down laws of practice, but it assumes to be, and really is the ruling power in cities and towns, governing all quarantine rules. Here, again, we know that not infrequently the orders given, if strictly followed, are very severe. Even with great severity they are impractical and in many instances are not supported by known facts.

For example, not a few local health boards have assumed that infantile paralysis was contagious, and often the carriers were young persons or adults, even though they showed no symptoms of the disease and did not subsequently acquire it. The specialist in pediatrics or nervous diseases might be appealed to, as he has been, to explain the nature of the disease and to guide and direct as to prevention and treatment. I, for one, am satisfied that it should not be he, but the wise general practitioner of large experience and well balanced views, who should finally counsel and direct, and to him and him alone, the others should be in the end subservient.

He may not—he cannot know as much in any particular line, as those we have mentioned, but he should be the presiding judge, and, after weighing all the factors involved, he has acquired the information and determined its relative value, in a way that can be done by no other physician. Therefore, in every health board, in every hospital, among the specialists of different sorts, the presiding and controlling man should be the all around physician.

Had this been the case, we should not have seen, as we have, the exaggerated terror prevalent in the late epidemic; we should not have had regulations of quarantine and care insisted upon which were illusory; we should not have had daily heralded in every newspaper the experimental doings from the latest researches of the laboratory, which may not prove ultimately of great practical value. We should have seen much greater attention paid to lifetime knowledge, acquired essentially in caring for patients. It is this bedside acquisition of a knowledge of drugs and their uses which, after all, is more important than anything else.

Further, we battle with disease successfully by doing the right thing at the right time and in the right way. It does not do to wait too long; it does not do to be a mere observer of what is being done in a few of our best equipped city hospital laboratories, and which can be accomplished only there or in connection with them, by a few very highly trained men with the very best opportunities and facilities.

Could immune blood serum be obtained from well selected donors in towns, villages, isolated country

tracts? Evidently not. If obtained in very limited quantities, could it then be used in such a way as to be really beneficial? I doubt it. We must not run wild about new findings. We must not believe that analogous studies and reports of laboratory research are as valuable as the knowledge acquired after many decades of experience, observation, and untiring service.

Firm, solid convictions, established by ourselves, but also inspired by, or proceeding directly from, the wise and broadminded physicians who preceded us and did nobly in the relief of human suffering and cure of disease, are simply invaluable.

42 West Thirty-seventh Street.

EPILEPSY.

By T. E. McMurray, M. D.,
Wilkinsburg, Pa.

In my limited experience with epilepsy, the following facts impressed me strongly.

1. Digestive disturbances, as manifested by foul breath, coated tongue, constipation, and intestinal gases.

2. The enormous appetite, especially for bread and sweets.

I decided to try a starch and sugar free diet. These patients received pancreatin and sodium bicarbonate at meals, a dose of epsom salts every fourth day, and mineral oil daily if needed to keep the bowels active.

The diet followed was that of diabetes until attacks subsided, when the food was gradually increased in amount. In only two cases was it necessary to give bromides, and in those cases only for a short time.

The subsequent history of my cases may be due to the pancreatin and soda, to the free evacuations of the bowels, or to the diet, or perhaps to all three, but in two of my cases convulsions returned after excesses at the table and disappeared when the diet was restricted again.

The cases all showed gastric hyperacidity, acidosis, but no glucose in the urine. A blood test for sugar was not made.

The three cases reported will give an idea of the course of the disease.

Case I. A. B., male, aged eighteen years, five feet five and a half inches in height; weight 128 pounds. Past history negative, except for convulsions, which began at five years of age. Began treatment, February 12, 1912. Had daily attacks for two weeks, when bromides forty-five grains in twenty-four hours, were given.

Attacks ceased about May 1st, when bromides were gradually decreased and diet increased until, July 1st, bromides were discontinued. No attacks until January 4, 1913, when four convulsions occurred and continued daily until January 10th. Treatment was instituted as at beginning, except the bromides. Saw patient frequently until March, 1914. Diet had been increased until he was eating anything except potatoes and bread. Patient left town March 15, 1915. No report since then.

Case II. C. D., male, eight years of age. Convulsions began at age of four years at intervals of two or three weeks. Began diet, etc., November, 1915. Two attacks in December, 1915, one in January, 1915, and none to date, September, 1916.

Case III. E. F., female, aged twenty-four years; attacks began at the age of eighteen years, three months after her securing a position in a bakery where she ate freely of candy and cakes. Attacks followed rapidly, four or five daily for several weeks, when they were controlled by bromides for about two months. After this they occurred two or three times weekly until January 2, 1915, when she began to diet. She was then taking ninety grains of bromide in twenty-four hours; this was cut to forty-five grains. Attacks continued at longer intervals until March, 1915, when they ceased until July 7, 1915. Had attacks July 7, 8, 13, 21, 1915. Following a picnic on July 4th, when she had eaten freely of usual picnic food, the diet was cut, but no bromides given July 7, 1915. No attacks since July 21, 1915, to date September, 1916.

It was rather hard to find a variety of food for my patients until I secured a copy of Hill's book on diabetes. I am now following his diets exactly as he advises for diabetes, and find it simplifies matters very much as I advise each patient to secure a book and to follow its instructions.

In addition to the three cases reported, there are five more who are showing marked improvement, and three in which treatment has just been started. These cases will be reported later.

POSTURES AND TYPES OF BREATHING EXERCISES.

With Reference to Their Effect on the Position of the Abdominal Organs; Fluoroscopic Studies.

By Nathalie K. Mankell, M. D.,
Buffalo.
And Edward C. Koenig, M. D.,
Buffalo.

Of late years many have recognized that ptosis of one or more of the abdominal organs may cause disturbances which sometimes disappear when the organs are corrected. Such correction of the organs has been attempted by the use of ptosis belts, fitted

Fig. 1.—Fatigue posture, slump. Fig. 2.—Exaggerated lumbar curve posture. Fig. 3.—Correct posture.

corsets, rest by lying on the back, Trendelenburg or knee chest positions, and by exercises. Operative measures have also been tried.

The authors during their work found cases where there were doubts as to the real effects of exercise

FIG. 4—First type of breathing; inspiration: chest up, abdomen out.

and postures upon internal organs, and were attracted by the ready means of proving their results to the Röntgen ray. In July, 1914, the attention of the American Posture League was called to the subject, and they appointed a committee of three to carry out this work in Buffalo.

Our committee planned a comprehensive study, to note the relation, shape, and motility of heart, lungs, and diaphragm, in addition to detailed study of the abdominal organs by means of the x ray. Numerous difficulties, however, modified the work.

Children were found to be easily distracted, and therefore not to be depended upon to meet the many requirements; so adults were chosen and taught the desired postures and exercises. Our subjects ranged in age from eleven to fifty years, the majority being between twenty and thirty years of age. They consisted of medical students, gymnasts from accepted training schools (both men and women), and schoolboys, with or without physical training. Some were of the decided long slender type, fewer of a short stocky type; the majority

FIG. 5.—First type of breathing; expiration; chest down, abdomen in.

approached the average height, weight, and proportions. There were no extremes as to sedentary or active habits. We studied fifty subjects, but as they were studied at different periods to observe results of treatment or more training, we have made seventy-three observations. We worked with three postures:

1. Fatigue posture or "slump" (Fig. 1).
2. Exaggerated lumbar curve posture (Fig. 2).
3. Correct posture with only slight dorsal and lumbar curves (Fig. 3).

Three types of breathing were used:

1. Complete deep breathing, costal, and diaphragmatic.

a. Inspiration, "chest up, abdomen out," filling the lungs and lowering the diaphragm (Fig. 4).

b. Expiration, "chest down, abdomen in," emptying the lungs and raising the diaphragm (Fig. 5).

2. Costal breathing with abdominal contraction:

a. Inspiration, "chest up, abdomen in," filling the upper part of the lungs mainly, but raising the diaphragm (Fig. 6).

b. Expiration, "chest down, relax abdomen."

3. Diaphragmatic:

a. Inspiration, "emphasis on lower ribs expanded, abdomen slightly out," filling the lower parts of the lungs and lowering the diaphragm (Fig. 7).

b. Expiration divided into two parts:

I. Abdominal muscle contraction first, "abdomen in" (Fig. 8).

II. Ordinary deep expiration, with ribs getting closer, and lower abdominal muscles still contracted, raising the diaphragm and emptying the lungs (Fig. 9).

FIG. 6.—Second type of breathing; inspiration: chest up, abodmen in.

Many different ways of recording results of the change and positions of the organs were tried. The use of tracing paper over the fluoroscope screen proved to be by far the most satisfactory method.

The objection to the use of plates in recording the results was that the subject could not remain near enough to the plate while doing a given exercise, and give a signal to the operator when all was ready for the exposure. Plates were tried, but resulted mostly in failures.

We found at the first examination of our fifty cases the situation of organs in the subjects' habitual posture, as follows:

a. The greater part of the stomach and all of the colon below the crests of the ilia. All apparently in the true pelvis in five cases; complete ptosis.

b. As above, but the splenic flexure and descending colon somewhat above the crest (left side) in twelve cases.

c. Cases where the hepatic flexure was approximately an inch above the crest (right side), the transverse colon sagging below the crest of the ilium, the splenic flexure midway between the crest and the ribs (left side), stomach a little above the crest, twenty-three cases; moderate ptosis.

d. Normal in ten cases.

1. Fatigue posture, "slump," invariably lowered

organs unless it was the habitual posture, or organs were so low that they scarcely could go any lower (Fig. 10).

2. Exaggerated lumbar curve posture, in six cases lowered more than "slump," in eleven cases less, in twenty-two cases they were equally low. In two cases it raised organs even higher than the correct postures. The last mentioned subjects had very flat backs and possibly not enough lumbar curve when they attempted the correct posture.

3. Correct posture (with two exceptions as stated above) raised the organs from one half inch to three inches to the highest position for that individual.

In twelve cases we tried other postures and exercises. For example, "stand tall" position, so frequently advocated. It raised organs if the abdominal muscles were contracted. If no other instruction was given but "stand tall," "grow," "make yourself as tall as possible," some would contract their abdominal muscles in the general effort to execute the order and elevate organs, others would make themselves tense all over, but would not contract the abdominal muscles enough to effect any elevation of organs. This method was seldom as effective as breathing (Fig. 11).

Lifting arms sidewise up or forward up, with or without ordinary deep breathing, was effective only when the exercise included abdominal muscle contraction, however high or wide the arms were stretched or whatever speed was used. It seldom was as effective as breathing (Fig. 12).

Abdominal muscle contraction alone, without any particular effort at deep breathing (done quietly and slowly) invariably raised organs from one to five inches. This was generally most effective in sub-

Fig. 7.—Third type of breathing: inspiration; mainly lower ribs expanded, abdomen slightly out.

Fig. 8.—Third type of breathing; expiration; *a*, abdomen in.

Fig. 9.—Third type of breathing; expiration; *b*, chest down in addition to abdomen in.

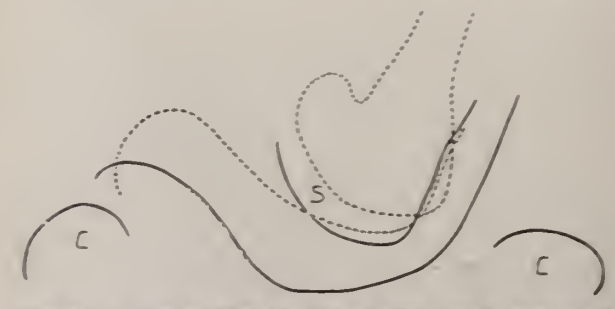

Fig. 10.—C, chest of [illegible] S, stomach; solid lines indicate chest and stomach during slump and exaggerated lumbar curve posture. Dotted lines indicate chest and stomach during correct posture.

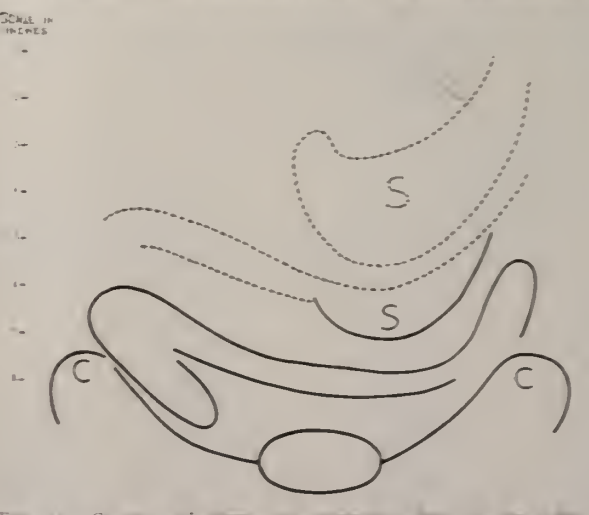

Fig. 11.—C, chest of same [illegible] Solid lines show chest and stomach in ordinary posture; dotted lines show chest and stomach while "stand tall" posture with forcibly contracted abdominal muscles is held.

jects with lax abdominal walls, i. e., protruding abdomens, and no training (Figs. 13, 14, and 15).

Studies of the breathing exercises showed:

1. Complete deep breathing, as described, invariably showed least effect, one half to one inch during expiration.

2. Costal breathing, with abdominal muscle contraction, elevated organs during inspiration from one to six inches. In nineteen cases it was the most effective elevation (Fig. 16).

3. Diaphragmatic breathing, as described, elevated organs from one to six inches during expiration. In twenty-six cases this was the most effective breathing. Since this was the most difficult type to learn, it is possible that the preponderance of success with this type might have been greater with longer practice of the breathing preceding the fluoroscopic observation. Variation of results, even with the same subject at the same session, was considerable, depending on training, flexibility, muscle control, and effort. Poor results at first trial were frequently overcome, as the subject became accustomed to surroundings. Reexamination after more training invariably showed more motility, if organs were not so low that the abdominal muscles could not affect them at all (Fig. 17).

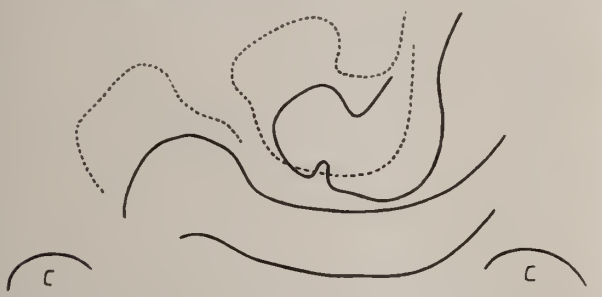

FIG. 12.—Crest of ilium. Solid lines show colon and stomach in correct posture. Dotted lines show elevation of colon and stomach, while arms are stretched upward and abdominal muscles are strongly contracted.

Elevation of organs was not uniform unless the organs were approximately in their normal positions If all the organs were in the true pelvis, no exercise whatever in standing position elevated them (Figs. 18 and 19).

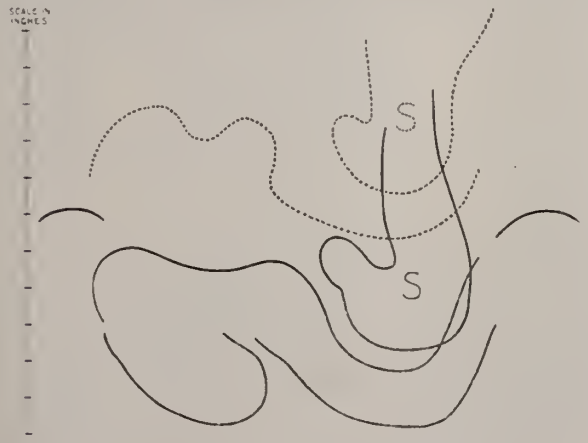

FIG. 13.—Solid lines show colon and stomach in slump posture, which was the habitual one in this subject. Dotted lines show elevation during strong abdominal muscle contraction in correct posture.

It is to be remembered that all these studies were done in the standing position.

Of particular interest to us was the fact that the second breathing (inspiration with abdominal muscle contraction) in some cases raised organs the most (chest high); whereas expiration in the third breathing, with abdominal muscle contraction held throughout (chest low) elevated organs in many more cases (Figs. 20 and 21). This is not to be confounded with the slump position, where the abdominal muscles are relaxed.

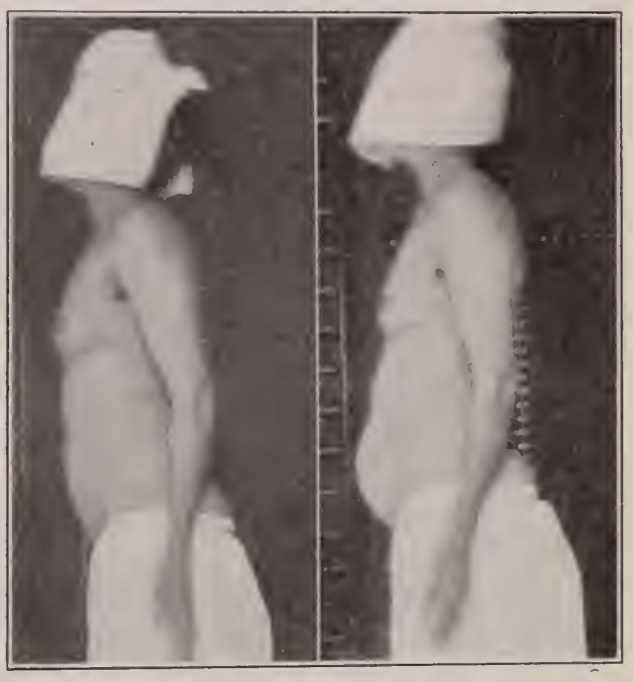

FIG. 14.—Abdominal muscle contraction.

FIG. 15.—Habitual posture.

Also abdominal contraction alone invariably raised organs, whereas "elevation cures," "stand tall" position, or "arms stretch exercises," were by no means always effective. This has given us a strong conviction that the abdominal muscles and their control is the greatest single factor influencing the position of the stomach and intestines. The position of the chest is only of secondary importance.

Of interest, also, were two cases in which moderate ptosis was found in July. In September, after a vacation spent in outdoor activity, both had their organs in normal position. Two weeks later one was again fluoroscoped, and once more ptosis was found. The subject was very tired that day, and had worked intensely for a few days. Neither habitually wore

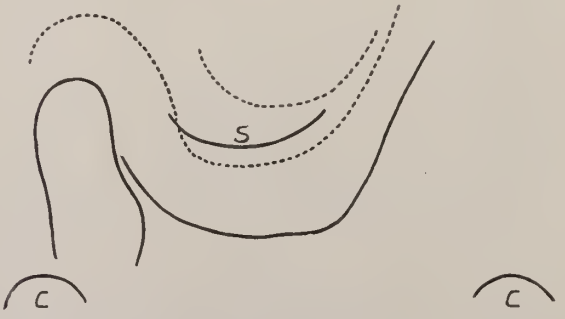

FIG. 16.—Second type of breathing. Dotted lines show elevation during inspiration. (See FIG. 6.)

corsets at any time, and both are careful that clothing does not compress or weigh down abdominal organs.

Our series embraced well trained gymnasium teachers with gymnastic or athletic training. Not a single case, with ordinary deep breathing, accomplished what deep breathing according to special instruction did. As this can be done at any time and in any good posture, providing that clothing does not restrict at the waist, it seems a valuable exercise. Corsets very loose above the umbilicus (not the patient's version of looseness) do not interfere.

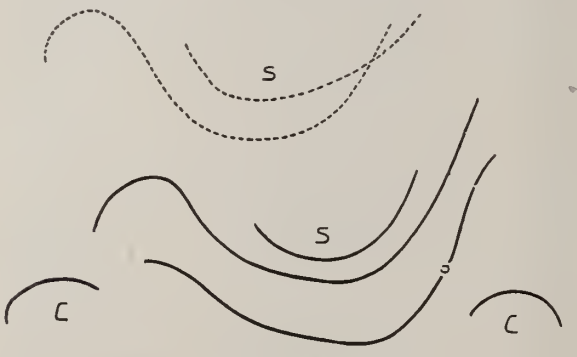

FIG. 17.—Third type of breathing. Dotted lines show elevation during expiration. (See Figs. 8 and 9.)

The fluoroscopic study of the correction and prevention of ptosis offers a large field for investigation. There is undoubted value in a more exact knowledge of the effect of exercise, clothing, posture, and appliances on the situation and function of the abdominal organs.

CONCLUSION.

We are aware that many factors influence the function of the stomach, intestines, and the other digestive organs. We are aware that many persons with pronounced ptosis may be apparently unaffected by that condition. We recognize the great tolerance and adaptability of the "human machine," so often suffering from postural defects. We also know of the great prevalence of such disturbances as constipation, low grade intestinal toxemia, atony of the intestines, retroversion of the uterus, and hernia. These certainly may be caused mechanically by constant forcing down of abdominal organs. There can be no advantage, and much disadvantage, in the low situation of these important organs.

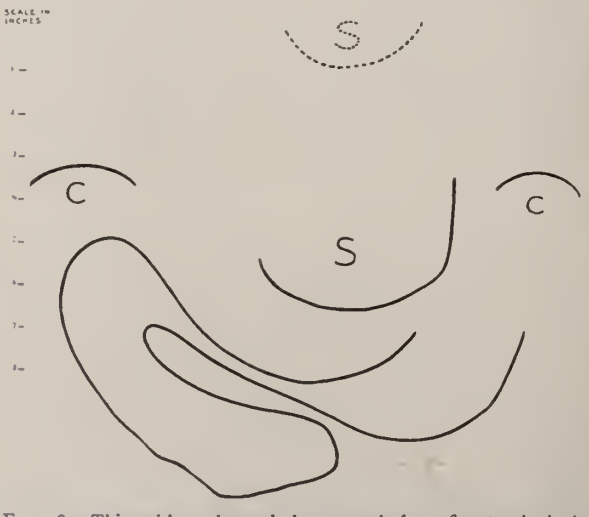

FIG. 18.—This subject elevated the stomach from five to six inches during expiration, third type of breathing, while the colon remained stationary.

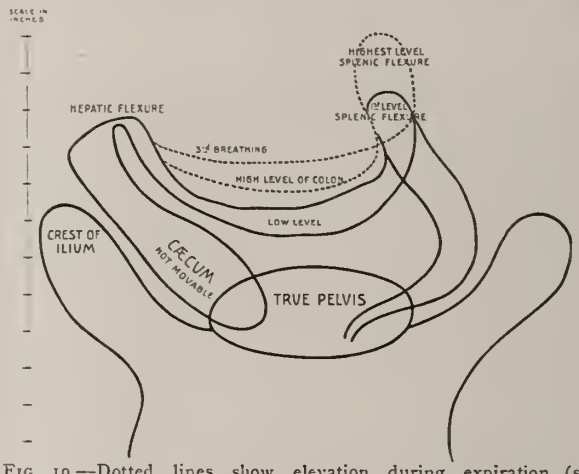

FIG. 19.—Dotted lines show elevation during expiration (see Figs. 8 and 9). The cecum and hepatic flexure were immobile while the stomach and splenic flexure could be elevated two or three inches. Later an operation was performed and a membrane was found holding the appendix down.

In standing, as well as in sitting and lying posture, abdominal contraction alone (done in a quiet, unhurried manner) elevates the organs from one to six inches. Thus we have an exercise that certainly is mild, but which when often repeated proves very effective.

The breathing exercises should be done quietly, in rhythm, somewhat like yawning. They may be repeated, if they do not cause fatigue, four to ten times; three to four times a day sometimes gives good results.

The general physical condition; muscle tone, good habitual posture, regular judicious exercises; clothing giving full freedom; these are undoubtedly large factors in the position and function of abdominal organs.

FIG. 20.—Second type of breathing; inspiration.

FIG. 21.—Third type of breathing; expiration completed.

THE RELATIONSHIP BETWEEN THE NERVOUS SYSTEM AND THERAPEUTICS IN PULMONARY TUBERCULOSIS.*

By Francis M. Pottenger, A. M., M. D., LL. D.,
Monrovia, Cal.,

Medical Director, Pottenger Sanatorium for Diseases of the Lungs and Throat; Professor of Diseases of the Chest; College of Physicians and Surgeons, Medical Department, University of Southern California.

Tuberculosis is an infection which may produce an inflammatory process in any organ or tissue of the body. This inflammation is chronic in nature, and, being produced by microorganisms, is accompanied by toxemia whenever activity is present. No matter what tissue is involved, other parts of the body are affected reflexly through the nerves which supply that particular organ. The disease is accompanied by a chronic toxemia, and as the toxins are elaborated, they express themselves through the nervous system, and particularly through the sympathetic nervous system, as I have shown elsewhere (1). If the organ involved is one that produces an internal secretion, this is interfered with by the inflammatory process; and, since many other organs brought indirectly into relationship with the disease process through the vegetative nervous system also produce internal secretions, there is a more or less general disturbance on the part of the internal secretions of the body; consequently there is commonly more or less disturbance in the metabolic activities that depend upon the secretions produced by the internal viscera.

The influence of acute and chronic infections upon the organism varies greatly. Acute infections may be accompanied by either slight or severe toxemia. Those which we know best, the acute infectious diseases, are accompanied, for the most part, by severe toxemia, but of short duration; consequently, the ultimate effect upon the organism is much less than that produced by such a chronic disease as tuberculosis, where the toxemia is more or less constant over a long period of time. The ill effects are due sometimes as much, and at times even more, to the results of the disease than they are to the disease process itself.

From our description it can well be understood that this infectious inflammation (through toxemia) produces disturbance in cellular activity throughout the entire body. By realizing the influence of the nervous system and the manner in which it is disturbed in tuberculosis, we are able to suggest rational measures for combating this disease, and to offer a rational explanation for the action of measures which have long been known to be of value in its treatment.

I have described many of the reflex disturbances which are noted in tuberculosis in a previous paper (2), in which I attempted to show the effects of the antagonistic action existing between the vagus and the sympathetic when both are stimulated by inflammation in the lung. I thus account for the instability of symptoms which are of reflex origin, and explain why at one time, we may have sympathetic tonus, and at another vagus tonus. This may be illustrated in the heart's action. It has long been known that the heart's action in tuberculosis is rapid. This statement must be modified. It is rapid whenever the reflex stimulation of the sympathetic nerves which supply the heart, plus the central toxic action upon the sympathetic, overbalance the reflex stimulation and overcome the slowing action of the vagus. When it does not do this the pulse rate is normal; or, if the vagus overbalances markedly, it may be even slower than under normal circumstances. Many tuberculous patients, who have a high pulse rate during the stage of increased toxemia, have a pulse rate in the sixties when this has passed by. (In order to determine this point the patient must be kept at rest.)

The same thing is true in the gastrointestinal tract. During periods of toxemia there is, as a rule, deficiency of secretion of not only the glands of the gastric and intestinal mucosa, but also of the large accessory glands, such as the liver and pancreas. There is also a decreased motility on the part of the gastrointestinal tract, leading to stasis and constipation. When the acute toxemia has passed and the patient is again clinically free from toxic symptoms, he may even have a better appetite than normally and the digestive process may be carried on more actively than under normal conditions. The explanation is that the vagus fibres which are reflexly influenced by the inflammation in the lung overcome the action of the sympathetic fibres which are likewise reflexly stimulated, causing increased secretion and increased motility. The symptoms of nausea and vomiting, which are sometimes present, are also indications of increased vagus stimulation.

Knowing that there is an antagonistic action between the vagus and sympathetic fibres wherever they meet in the internal viscera, and knowing that both are stimulated by the inflammation in the lung, we can readily understand the variability of the symptoms given below, as they manifest themselves in the various internal viscera (Group II).

Aside from a few minor changes I previously offered the following classification of the symptoms in tuberculosis (3).

Group I. Symptoms Due to Toxemia.	Group II. Symptoms Due to Reflex Action.	Group III. Due to Tuberculous Involvement *per se.*
Malaise	Hoarseness	Frequent and protracted colds
Lack of endurance	Tickling in larynx	Spitting of blood
Loss of strength	Cough	Pleurisy
Nervous instability	Digestive disturbances	Sputum
Headache	Loss of weight	Fever
General aching	Circulatory dsturbances	
Lack of appetite	Chest and shoulder pains	
Digestive disturbances	Flushing of face	
Loss of weight	Apparent anemia	
Rapid heart's action		
Night sweats		
Fever		
Anemia		

When toxemia is very severe, producing collapse there results—Vasodilatation (vasomotor paralysis), sweating, and subnormal temperature.

The most pronounced effect on the nerves is produced by toxemia, as seen from the symptoms detailed under Group I. The effect of toxemia is widespread; and, if we consider the further changes that occur in advanced tuberculosis which result in the production of neuroses and psychoses, we

*Read before the Seventeenth Annual Meeting of the American Therapeutic Society, Detroit, Mich., June 9 and 10, 1916.

can see that there is a general tendency for toxemia to express itself on the central nervous system, producing cell exhaustion. We can see, further, that the syndrome of toxemia is, for the most part, that of general sympathetic stimulation. Malaise, lack of endurance, general nerve irritability may be due to general central stimulation, as well as to the action upon the sympathetics. The remaining symptoms, however, seem to be definitely those of general sympathetic irritation.

In my previous papers I discussed the etiology of the individual symptoms in Group 1, and, with the exception of fever, accounted for them as being due to sympathetic stimulation. I could not at that time explain the action of toxins in the production of fever, yet I felt that fever was an integral part of the syndrome of toxemia. Being convinced that such was the case, and noting that fever was accompanied by the other symptoms which are definitely of toxic origin, I continued my study until I am now able to suggest a theory for its production, which is in harmony with the explanation of the other symptoms.

Fever may be due to either an increased production of heat or to a decrease in elimination of heat. An increased amount of heat is produced in the body by the consumption and oxidation of extra amounts of food, and by increased metabolic change, which is accompanied by increased chemical action. Heat is dissipated through perspiration, respiration, urination, and defecation. A certain amount of heat is also used up in warming foods and drinks which are below body temperature when consumed.

The studies of many workers, but notably Vaughan's (4) work show that the various proteins derived from bacteria when injected parenterally into experimental animals, produce toxic symptoms, including fever. With the injection of small quantities of protein, the toxemia is insignificant, and the rise of temperature slight. If the dose be larger, the toxemia is greater and the rise in temperature likewise greater. If the introduction of protein is limited to one injection, the syndrome of toxemia is of short duration. If the injection is repeated at frequent intervals, the syndrome is continuous. If large quantities of protein are injected at one time, the toxemia is very severe and collapse may result. Vaughan has shown experimentally that every type of temperature found in infections may be reproduced by varying the methods.

Let us inquire what there is about an injection of foreign protein to cause an increase in temperature? Can we imagine that the injection of infinitesimal doses of protein will cause sufficient metabolic activity and produce chemical change sufficiently marked to elaborate large quantities of heat? Does it not seem impossible that two or three mgs. of tuberculin could produce sufficient increased heat production to account for a rise in temperature to 103° F., as the writer has seen, without there being, at the same time, an interference with heat elimination? The enormous amount of heat required for such a rise in temperature, if increased production is the main factor in causing the rise, can be realized only when we call to mind that it requires about ten per cent. increase in body temperature to produce one degree of rise in temperature. In other words, a temperature of 103° F. means an increase in temperature of 5° F. or a total increase equivalent to about forty-five per cent. of the total body heat of the normal individual.

There are several facts which lead me to believe that the more important factor in the production of fever is an interference with normal heat dissipation rather than an unusually active heat production. In support of this theory I offer the following facts:

1. The experimental introduction of protein produces a general sympathetic stimulation.

2. The manifestations of clinical toxemia are those of general sympathetic stimulation.

3. It has been noted in experimental animals that when protein is injected parenterally, there is a constriction of the vasomotors of the surface, as determined by the constriction of the vessels of the ear of the rabbit (Jona).

4. A rise of temperature is accompanied by other symptoms of toxemia, and by constriction of the superficial bloodvessels which, at times, manifests itself by a sensation of chilliness.

5. The action of toxins and epinephrine is practically the same; both act chiefly upon the nervous system. The introduction of epinephrine causes a constriction of the superficial bloodvessels and a rise in body heat.

From these facts I am led to believe that the rise in temperature which occurs in infections, or whenever a foreign protein of any type is introduced parenterally into the body of either man or animal, would not occur apart from their action through the sympathetic nervous system, which produces a general vasoconstriction of the superficial bloodvessels, and interferes with the dissipation of heat. I am further convinced of this from the fact that emotional states, particularly the depressive emotions, such as those of fear, disappointment, anxiety, discontent, and worry, produce a general sympathetic stimulation; and that all of these depressive conditions are associated with a rise in temperature, at least in the tuberculous patient. Further proof is shown by the phenomena which occur when intense toxemia is present. Here, instead of a rise, we have a fall in temperature, and the patient's body is covered with perspiration, which indicates a general vasomotor relaxation, attended by perspiration and rapid loss of heat. This vasodilatation effect is due to a condition approaching vasomotor paralysis and probably results from a state of exhaustion of the nerve centres caused by the action of the toxins.

Our knowledge of the changes in internal secretions in tuberculosis is meagre. We do know, however, that there are certain definite changes upon the part of many of them; for example, there is a decreased secretion of gastric juice; a decrease in the activity of the liver and pancreas and glands of the intestinal mucosa. We also know that there is increased activity on the part of the adrenal glands whenever there is sympathetic stimulation. We also note that there is an increase in the size and activity of the thyroid gland in many infections, and that enlargements of this organ are found in quite a large proportion of early cases of clinical tuberculosis. The effect of these altered secretions cannot be dwelt upon at this time, because of our meagre knowledge.

Suffice it to say that the action of increased adrenal secretion in the blood is to produce the same phenomena as depend upon sympathetic stimulation for their existence. Physiologists have shown that the hormone in epinephrine acts peripherally, while toxins act centrally. It acts upon the myoneural junction of the sympathetics. Thus, epinephrine, acting peripherally, will cause dilatation of the pupil, relaxation of the musculature of the bronchi, decrease in the motility of the stomach and intestines, and also a decrease in the secretion of the various glands of the gastrointestinal tract.

With this discussion of the nervous system in its relationship to tuberculosis, we may ask, how can these various pathological activities be corrected therapeutically? If we are able satisfactorily to answer that question, we shall be able to offer a rational explanation of the action of measures which are of known therapeutic value in this disease.

Bearing in mind that our therapeutics of tuberculosis today is indirect, that we have no remedy which acts specifically upon the tubercle bacillus, like quinine in malaria, or salvarsan and mercury in syphilis, we are obliged to bring about favorable results by building up the natural resisting powers of the patient and by introducing measures which tend to increase fibrosis. Among important measures which act by improving the natural resisting power are those which control excessive stimulation of the sympathetic nervous system. Such measures relieve the inhibiting action upon the various structures which it controls and permit the natural functions to be carried on more advantageously.

Since sympathetic stimulation is produced by toxins, no matter what their source, we may find it in tuberculosis as a result of the absorption of protein from the bacillus itself, probably also as a result of the absorption of destroyed tissue and any other bacteria that may complicate the process. While toxemia cannot be caused by the depressive emotional states, yet these produce sympathetic stimulation and act in the same manner as toxins; consequently, they must also be relieved in the same way as toxemia, if we wish to relieve the organism from the inhibiting action of the sympathetic system.

Tuberculous toxemia is present chiefly during the stage of active tuberculosis. The body will accustom itself, apparently, to a certain amount of toxemia without producing the syndrome which usually accompanies it; consequently, if activity in the tuberculous focus is of slight degree, or if it has passed and a degree of quiescence has been attained, toxic symptoms do not appear if the patient is kept at rest. If the patient is allowed to engage in exercise, however, even at this time of quiescence, symptoms of toxemia will appear.

We shall now endeavor to point out how some of the important remedial measures in tuberculosis relieve the conditions above described.

Open air. We know that there is nothing specific in open air. It is not the increased amount of oxygen in the air that cures tuberculosis. The victim of tuberculosis can obtain all the oxygen that is required for carrying on the functions of the body in a closed room. Sufficient exchange of air will take place through the unavoidable openings to keep the air sufficiently fresh to supply all the oxygen that is necessary. Neither is it the amount of carbon dioxide in the closed, compared with the open room, that makes the open air more desirable; the percentage of carbon dioxide would remain sufficiently low to keep the air free from deleterious effects if the room were closed; and, even if it were hermetically sealed, there would still be sufficient air to maintain the patient for quite a time, depending on the size of the chamber. There is, however, a distinct stimulation of metabolism produced by the action of the circulating air upon the body surface, which relieves heat stagnation within the body, stimulates metabolic activity, and improves the general cellular tone, and this is accompanied by improved rest and sleep. As a result there is an improvement in the general tone of the patient. He becomes encouraged, and to that extent his sympathetic stimulation is decreased and his condition is improved.

Rest. Rest is essential in treating toxemia. It is valuable whenever exercise increases the sympathetic stimulation by pouring forth into the tissues an increased amount of toxins. Thus, under rest, we note that patients with rapid heart action, poor appetite, deficient digestive activity, constipation, and rise of temperature, may experience an improvement, or even lose all of these symptoms; and, as they disappear, encouragement follows and a general improvement takes place. This beneficial effect of open air and rest may be entirely counteracted by fear, discontent, anger, or worry on the part of the patient; because it continues to produce sympathetic stimulation and depressed function on the part of the important viscera, in spite of the fact that otherwise they would be relieved by rest in the open air.

Psychotherapy. Often it is impossible to relieve toxemia. The disease is in such a high state of activity that toxins are continuously thrown into the general circulation. Patients who are suffering from this greater activity are often depressed and discouraged. While we cannot immediately check the formation of toxins, or counteract their effect upon the sympathetic system, we can relieve the patient of the sympathetic stimulation which comes from his depressed mental state. If we can only encourage and give him some positive suggestion, we may often produce great improvement in his general condition. We shall at times relieve the sympathetic stimulation to such a degree that the functions of the body are carried on to advantage and the patient regains his physiological balance, in spite of toxemia. Positive suggestion is an important measure with which to treat a long drawn out chronic toxemia. The influence of friends is usually harmful, because they have so many things to suggest which lead to discouragement, discontent, and worry; and a well directed psychotherapy, replacing negative suggestion by positive suggestion, is a powerful factor in improving the patient's general condition.

Food. The influence of food may be greatly enhanced by relieving the sympathetic stimulation due to toxemia and depression. We usually note that the appetite and digestion, and therefore nutrition

of the patient, improves when he is put at rest in the open air, and receives hope and encouragement.

Exercise. There is a time when exercise has an important and beneficial influence upon the patient. Exercise calls for increased metabolism. Increased metabolism is met by increased food intake; consequently, after toxemia has passed and the patient can exercise without manifesting toxic symptoms, his nutrition can be greatly improved by permitting exercise. The effect of exercise upon the nervous system may not be quite as readily grasped as that of the other measures mentioned. Every cellular activity is produced by nerve action; consequently, the increased appetite and generally improved metabolism are brought about through a stimulation of the nervous system.

Baths. The effect of baths, either air, sun, or water, is exerted through the nerve endings in the skin and extends to every cell of the body. If the activity in the skin is well cared for, as it may be through the stimulating effect of water, light, or air, the vasomotor tone is improved, the metabolic activity of the patient's cells is hastened, and the elimination of heat, moisture, and various toxic products is accelerated.

JOINT HYPOTONIA.

With Congenital and Familial Manifestations.

By Harry Finkelstein, M. D.,
New York,
Adjunct Orthopedic Surgeon, Hospital for Deformities and Joint Diseases.

The foregoing title is best descriptive of a unique case that recently came under the observation of the author, being the first of its kind seen during ten years' service at the Hospital for Deformities and Joint Diseases.[1] The characteristic feature is a striking degree of joint mobility involving practically all the joints of the body without apparent demonstrable muscle weakness. The history is as follows:

Case. S. J., female, twenty-one months old. Family history: Grandmother, two uncles, and mother had flail joints when young, which improved with adolescence. The mother, aged thirty years, still presented a laxity of the wrist joints. (Fig. 1.) In all other respects she was normal. She had two children, the youngest, two weeks old, who at the present writing showed no joint abnormalities. Previous history: Patient was born at full term, noninstrumental delivery, weight, six and a quarter pounds. Breast fed for sixteen months. Dentition somewhat tardy; began walking at the age of nineteen months. With the exception of several minor ailments, such as abscess of neck and peritonsillar abscess, had enjoyed good health. Present history: Since birth, child had had flail joints, the upper and lower extremities being especially involved, the spine to a lesser degree. Muscular power unimpaired.

Examination showed general condition to be good. Body and limbs well developed. Length, thirty-four inches. Child sat erect. Walked with a decided waddling gait due to relaxation of the hip joints, resembling closely the double congenital hip walk. Examination of the chest and abdomen failed to reveal abnormal conditions. Thymus not enlarged; no evidences of rickets; child playful and intelligent.

Fingers soft and extremely flexible. Each individual phalangeal joint could be hyperextended to a marked degree. The back of the fingers could be brought in apposition with the dorsum of the hand. The same condition prevailed at the wrist joint, where the back of the hand could be brought in contact with the extensor surface of the lower forearm (Figs. 2 and 3). The elbows could be hyperextended, and there was a much wider range of motion in the shoulders than normal.

Fig. 1.—Showing laxity of wrist joint in mother.

When standing, the feet were held in marked pronation (Fig. 4), and on passive motion the feet could be inverted, everted, and dorsiflexed, to a most unusual degree. The dorsum of each foot could easily be brought in contact with the lower portion of the crest of the tibia, without producing pain or discomfort. (Fig. 5.) The knees could be hyperextended (Fig. 6), and both hips were subluxated, as shown in the radiograph; they could be dislocated and reduced without effort. The measurements of the limbs showed no dissimilarity in either length or circumference.

The report of the examination by Dr. Charles Rosenheck, attending neurologist to the hospital, was as follows:

Fig. 2a.—Showing extreme mobility of phalangeal and wrist joints.

"The child uses its limbs freely, holds its head erect, walks without difficulty, and apparently presents no minor or gross motor disturbances. She performs many and varied muscular acts consistent with her age with perfect freedom and coordination. There are no gross psychic de-

[1] From the service of Dr. Henry W. Frauenthal, to whom I am indebted for the case.

fects apparent on observation or by close questioning of the patient's mother in regard to disturbances of the intelligence. There are no cranial nerve disturbances, and the pupils react with promptness to light and accommodation. The individual muscle bundles are firm, the contour is normal, and there are no atrophies or undue enlargements of the larger muscular groups. The electrical reactions

FIG. 2b.—Showing extreme mobility of phalangeal and wrist joints.

are normal, the muscles responding briskly to the interrupted and continuous currents either when individual muscles are tested or muscles *en masse*. The reflexes are prompt and equal in all the extremities. The patellar and Achilles reflexes are quite lively. There are no pathological reflexes elicited such as the Babinski or ankle clonus."

These findings were corroborated by Dr. J. Victor Haberman, who has been particularly interested in the neurological phase of this subject and who courteously examined the patient at my invitation in order to rule out the possibility of its being a case of myotonia congenita, which it apparently resembled on first impression.

Although there have been numerous instances of relaxation occurring in one or several joints, either congenital or acquired, a review of the literature failed to reveal a case similar to the one described above. The nearest approach to it is in the condition described by Oppenheim, in 1900, as myotonia congenita, of which there are at present about seventy cases on record. The characteristic features of this disease are:

FIG. 3.—Showing extreme mobility of fingers and wrist; complete hyperextension.

1. Observed during the first two years of childhood (in most cases, apparently dating from birth, i. e., congenital).
2. Hypotony up to complete atony of muscles.
3. Partial or complete loss of tendon reflexes.
4. Impairment of active motion, in some cases, even complete cessation.
5. Electrical examination showing from a slight quantitative change to even complete disappearance of response with electrical currents; but never reaction of degeneration.
6. Flail joints, if present, are due to muscular weakness.
7. No sensory disturbances.
8. About one third of the reported cases terminated fatally from pneumonia or other intercurrent diseases; the remaining cases showing a tendency to spontaneous though slow improvement.

Haberman has reported three cases of myotonia from the Oppenheim Polyclinic at Berlin; the first two were typical cases corresponding to the foregoing symptomatology. The third case was that of a girl eighteen months old, who was unable to stand, sit, or hold up her head. Sucking was difficult. Breathing was hoarse. When let go, the child doubled up as if made of rubber. The upper extremities were flabby, lacking all tone, though some movements were evident. When raised, they fell back on the table. No reflexes were present. The legs were absolutely atonic; patellar and Achilles reflexes were absent; passively lifted, they fell back as if lifeless. The muscles were hypotonic. There was considerable adiposis. Sensations were normal. Electrical examination showed great lessening of irritability for both currents in the lower extremities, less marked in the upper. The atony of the muscles of the back, hip, and knee was intense. Dunn states that out of forty cases of myotonia, twenty-two occurred during the first two years of

FIG. 4.—Showing pronation of feet on standing.

life, eighteen during later childhood up to ten years. Foot described a case in which the tendon reflexes were diminished but not absent, and in which there was obesity, flaccidity of the legs, and enlarged thymus. Two other children were similarly affected in the same family. Councilman and Dunn, under the heading, Myotonia congenita, describe a condition characterized by flaccid paralysis, mostly in the legs, and difficulty in deglutition. Sensations were normal; no reaction of degentration. They state that reflexes may or may not be present.

SUMMARY.

It is, therefore, evident that my case differs in nearly all its essentials from Oppenheim's myotonia congenita. It is not only congenital, but familial as well. There is no interference with the motor power, not even a weakening of the muscles, nor is there any loss of reflexes. The electrical reactions

are normal. Nearly all the joints of the body are involved. The radiograph shows no evident lesions in the bones. The only structures affected are the capsules and ligaments of the joints. The prognosis, judging by the progressive improvement which occurred in the other affected members of the family, is favorable.

FIG. 5.—Showing mobility of feet on passive manipulation.

We frequently encounter among acrobats and circus freaks cases resembling the author's case, in that they combine both muscular strength and excessive mobility of joints, commonly designated as "double joints." They may be congenital or acquired, and often occur in several members of a family. Whether a course of physical training with the purpose of increasing the mobility of the joints, and begun during childhood, is the causal agent or whether there is some definite organic change, is unknown.[2]

That so extensive a case of joint hypotonia as described above is exceedingly rare, is attested by the fact that it is the only one of its kind that has come before the author's observation in a decade, and also that no similar instance has been cited in the literature.

[2] So called double joints are usually due to an unusual length of the ligaments about them.—EDS.

ACUTE MASTOIDITIS.*

By Harold Hays, M. D., F. A. C. S.,
New York,
Assistant Surgeon in Otology, Eye and Ear Infirmary; Assistant Otologist and Laryngologist, City Hospital.

There is no condition which the general practitioner confronts with more alarm than acute mastoiditis. This is readily explained by the fact that few physicians have confidence in their ability to examine an ear properly. The fault is not theirs; it is inherent in the poor training in otology that is given the average man in the medical school where the specialties until recently received little consideration.

I well recall my own experience. After four years spent in one of the best medical schools, and three years spent in the surgical wards of one of the best hospitals, in which were twenty beds devoted to patients suffering from ear troubles, I went into practice with absolutely no knowledge of a proper examination of the nose, throat, or ear.

Times have changed, however. The medical schools realize the importance of a proper examination of these parts, and make use of the new inventions, particularly the electrical, which make an examination of the ear a very simple procedure. The electroscope allows us to see the ear drum so plainly that no mistake can be made in demonstrating various pathological conditions.

In an institution like the New York Eye and Ear Infirmary, we see thousands of acute ear cases a year, and between five and eight hundred patients are operated upon for acute mastoiditis. In proportion to the population of Greater New York, the number of cases of acute otitis media is very small, and the proportion of patients who suffer from acute mastoiditis, after having an acute otitis media, is only about one in fifteen. From this we can see that today the number of cases that a single practitioner sees in the course of a year is very small. We hear of mastoiditis oftener today, because it is recognized earlier.

There was a time when a running ear was considered a negligible factor in childhood; after measles or the other exanthemata it was a common occurence. Today, every physician views a discharging ear with apprehension, realizing the seriousness of complications, and tries in every way to cure the condition.
